ABSTRACT

Low-ionization-state far-infrared (FIR) emission lines may be useful diagnostics of star formation activity in young galaxies, and at high redshift may be detectable from the ground. In practice, however, very little is known concerning how strong such line emission might be in the early Universe. We attempted to detect the 158-\( \mu \)m [C II] line from a lensed galaxy at \( z = 4.926 \) using the Caltech Submillimeter Observatory. This source is an ordinary galaxy, in the sense that it shows high but not extreme star formation, but lensing makes it visible. Our analysis includes a careful consideration of the calibrations and weighting of the individual scans. We find only a modest improvement over the simpler reduction methods, however, and the final spectrum remains dominated by systematic baseline ripple effects. We obtain a 95 per cent confidence upper limit of 33 mJy for a 200 km s\(^{-1}\) full width at half maximum line, corresponding to an unlensed luminosity of \( 1 \times 10^9 \) L\(_\odot\) for a standard cosmology. Combining this with a marginal detection of the continuum emission using the James Clerk Maxwell Telescope, we derive an upper limit of 0.4 per cent for the ratio of \( L_{[\text{CII}]}/L_{\text{FIR}} \) in this object.

Key words: galaxies: evolution – galaxies: formation – galaxies: high-redshift – cosmology: observations – submillimetre.

1 INTRODUCTION

Low-ionization-state far-infrared (FIR) emission lines play an important role in cooling star-forming regions, and they allow us to infer the flux of rest-frame ultraviolet (UV) photons. Star-forming galaxies have large dust masses which obscure UV radiation, so we rely on the IR and longer wavelengths to probe these star-forming regions. Studies have shown that [C II], the ground-state fine-structure line of singly ionized carbon (\( ^2\text{P}_{3/2} \rightarrow ^2\text{P}_{1/2}, \lambda = 157.7409 \) \( \mu \)m), is the dominant cooling line in gas-rich star-forming regions (Dalgarno & McCray 1972; Crawford et al. 1985; Stacey et al. 1991). It is thus expected to be a probe of star formation in young galaxies. In some nearby galaxies the [C II] line accounts for as much as 1 per cent of the far-IR luminosity (Stacey et al. 1991; Nikola et al. 1998; Mochizuki 2000). On the other hand, in some more distant ultraluminous infrared galaxies (ULIRGs) results from ISO indicated much lower fractions (Malhotra et al. 2001; Contursi et al. 2002; Luhman et al. 2003). At \( z \simeq 5 \) we know very little concerning the physical conditions within star-forming galaxies. Metallicity, UV flux, dust content and geometry could all be radically different from that for more nearby (and hence cosmically older) systems. In the absence of much empirical data, even upper limits on [C II] luminosities are therefore worthwhile. [C II] is the brightest line in our Galaxy (Mizutani et al. 1994), but its wavelength makes it impossible to observe from the ground. At high redshift, where the line is redshifted into the submillimetre range, there is great promise for using this line to probe early galaxy evolution, or even to find the first objects (e.g. Stark 1997; Sugimoto, Sugimoto & Spergel 1998). Until instruments with much wider back-ends and greatly improved sensitivity become available, progress can only be made slowly, by targeting individually promising objects.

The \( z = 4.926 \) lensed galaxy, detected as a red arc in the cluster CL 1358+62 (referred to as ‘G1’ in Franx et al. 1997, hereafter F97), magnified by a factor of 5–11, represents a particularly promising target for observing [C II] from the ground. Its redshift places the line at an accessible frequency (\( \simeq 320 \) GHz), though not ideal as it is on the edge of an atmospheric water line. The galaxy has a reasonably high inferred star formation rate (\( \simeq 36 \) M\(_\odot\) yr\(^{-1}\), F97), and unlike quasars observed at similar redshifts, the [C II] line is expected to be close to the systemic redshift of the galaxy. Moreover, although rest-frame UV colours indicate significant reddening, there is little submillimetre continuum detected, with a 3\( \sigma \) upper limit of 4 mJy (van der Werf et al. 2001, but see Section 4).

In the following paper we discuss the analysis and interpretation of our data. Section 2 briefly describes the observing programme. Section 3 describes the specifics of our analysis procedures. The results are presented in Section 4 and discussed in Section 5.

2 OBSERVATIONS

Object G1 was targeted with the Caltech Submillimeter Observatory (CSO), located at 13 300 feet on the summit of Mauna Kea in Hawaii, over three nights in 1998 January. The telescope is a 10.4 m f/0.4 submillimetre antenna with an alt-az mount.

The atmospheric transmission during the observing run, as measured by the CSO $\tau$ meter at 225 GHz, was very good. The optical depth ranged from $\tau_{225} \approx 0.03$ to 0.07, corresponding to an optical depth at 320 GHz of 0.32–0.55.

2.1 Frequency centre

F97 determined the redshift of G1 from the detection of Ly $\alpha$ emission at 7204 Å, giving $z = 4.926$. They note, however, that the Ly $\alpha$ line is asymmetric and that the measured Si II absorption line is blueshifted by $\approx 300$ km s$^{-1}$. These features can be explained by an outflow model, whereby an expanding shell of neutral and ionized material absorbs the blue side of the Ly $\alpha$ line (e.g. Lequeux et al. 1995). We assume that the [CII] emission would be somewhere between the Ly $\alpha$ and Si II lines, and therefore centred the detector shifted $\Delta v \approx 200$ km s$^{-1}$ from the Ly $\alpha$ centre, or $z = 4.922$. This is a reasonable assumption, as this shift is typical of linewidths observed in local galaxies. The [CII] emission line is redshifted to $v_0 = 320.939$ GHz for the expected centre of our source.

2.2 Instrumentation

Based on the calculations of the previous section, it is clear that the CSO 345-GHz receiver is the appropriate detector. This receiver is a single side-band SIS mixer with 1-GHz IF, and acousto-optical spectrometer (AOS) backends. For our observations the signals from the mixer were sent to three spectrometers simultaneously, with 50-, 500- and 1500-MHz bandwidths.

From the F97 detection of Si II in CL 1358+62-G1, we assume that the [CII] line is $\approx 200$ km s$^{-1}$ wide, corresponding to 200 MHz at our observing frequency. We therefore concentrate our efforts on the data from the 1500-MHz receiver, use the 500-MHz data as a check on our observing frequency. We therefore concentrate our efforts on the data from the 1500-MHz receiver, use the 500-MHz data as a check on the source scan variances all correlate well, and that they track the 500-MHz data.

On the first night the receivers were centred on the nominal line centre, 320.939 GHz. In an attempt to avoid confusing any systematic detector response with the shape of the emission line, the receiver was shifted by $\Delta v = 129.8$ km s$^{-1}$ for the second and third nights.

The secondary mirror chop throw was set to 60 arcsec at 1.123 Hz on the first night. It was apparent that after observations of one night we had reached near the instrumental noise limit, so we set more conservative chop parameters, 40 arcsec at 0.7 Hz, on the second and third nights in an attempt to probe systematic effects. By changing the chop throw, we additionally decrease the probability of inadvertently chopping on to a nearby source.

2.3 Pointing and calibration

The telescope was pointed at $\alpha = 13^h 59^m 39.0^s, \delta = 62^\circ 30^\prime 47^\prime\prime$. This position was determined by visually comparing the Hubble Space Telescope (HST) image presented in F97 with coordinates of pointings did not dominate the error budget, we might expect method (iii) as the most elegant solution. If baseline variations did not dominate the error budget, we might expect method (ii) to yield the best results, and we would advocate its use in general for low signal-to-noise ratio data.

3.2 Data reduction

The data are co-added within each night. First, a zeroth-order baseline, fit to the wings of the spectrum, is subtracted from each source

Table 1. Details of observations. Row 1 shows the line centre of the receiver on each night. The rest of the table displays the number of usable scans taken on each night in each detector.

4 RESULTS

It is clear from Fig. 2 that the error bars are much smaller than the structure in the final spectrum. The systematics in the instrument prevent integrating down to such low noise levels. We re-estimate the error bars by finding the best-fitting Gaussian and scaling the errors so that $\chi^2 = N$, where $N$ is the number of degrees of freedom in the fit.

A full four-parameter Gaussian fit will not converge to a meaningful result, so we instead fix the line centre and width to the a priori expected values of $v_0 = 0$ km s$^{-1}$ and full width at half maximum (FWHM) = 200 km s$^{-1}$ (as described in Section 2.1), and calculate the baseline as the weighted average of the data outside $\pm 2\sigma$ of the line centre. We find a 95 per cent upper limit of 33 mJy using the 1500-MHz receiver; the 500-MHz receiver gives consistent, although less constraining results. To convert from specific flux $S_\nu$ to luminosity $L$, we first integrate over frequency, $S = \int S_\nu d\nu = 1.06 S^{\text{peak}} \times \text{FWHM}$ for a Gaussian of height $S^{\text{peak}}$ and width FWHM = $v_0(\Delta v/c)$, then multiply by $4\pi D_L^2$, where $D_L$ is the luminosity distance for a given cosmology. For a standard cosmological model with $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$ and $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, we find $D_L = 45.8$ Gpc and $L_{\text{[CII]}} = 5.4 \times 10^9 L_\odot$.

We also rereduce existing SCUBA observations at 850 μm (Holland et al. 1999) to find an estimate of the total FIR luminosity, $L_{\text{FIR}}$. An 850-μm upper limit of $S_\nu < 4$ mJy was reported by van der Werf et al. (2001) based on 4 ks of pointed photometry data. We combine 15 ks of jiggle-map data ($\sim 2.5$ mJy rms) with the photometry data ($\sim 1.5$ mJy rms) using the methods described in Borys et al. (2003) and find a 2.1σ peak 2 arcsec from G1, well within the 15-arcsec beam. Although not highly significant, and in a blank field survey we would not consider a 2σ peak a detection, this is a pointed measurement of a known source, so we consider this a measurement rather than simply an upper limit. We can then calculate the ratio $L_{\text{[CII]}}/L_{\text{FIR}}$ using Gaussian probability distributions to describe both $L_{\text{[CII]}}$ and $L_{\text{FIR}}$. Integrating a grey-body model with $T_{\text{dust}} = 40$ K and $\beta = 1.5$ (Combes 1999; Klaas et al. 2001) from 8 to 1000 μm, we then find that the SCUBA measurement $S_{850} = (2.8 \pm 1.3)$ mJy corresponds to $L_{\text{FIR}} = (2.4 \pm 1.2) \times 10^{12} L_\odot$, assuming the same cosmology as above. Integrating over the joint probability, we find a Bayesian 95 (99) per cent upper limit $L_{\text{[CII]}}/L_{\text{FIR}} < 0.4$ (1.1) per cent.

5 DISCUSSION

Typical values of $L_{\text{[CII]}}/L_{\text{FIR}}$ are thought to be $\sim 0.1$–1 per cent, but there is recent evidence to suggest that it can be lower, especially for ULIRGs, which are thought to make up a large fraction of the high-redshift submillimetre population. We find $L_{\text{[CII]}}/L_{\text{FIR}} < 0.4$ per cent at 95 per cent confidence for our particular target. While this does not rule out the ratios found by Stacey et al. (1991), it does...
confine the ratio for this particular high-redshift galaxy to the lower end of the range.

Based on their lensing model, F97 determine that the source G1 is magnified by a factor of 5–11. Taking the lower end of this magnification range, we find an unlensed luminosity of \( L_{\text{[C II]}} < 1 \times 10^9 \, L_\odot \). We can use the absolute \( L_{\text{[C II]}} \) measurement to place an upper limit on the star formation rate (SFR) occurring in the source. Boselli et al. (2002) relate SFR to \( L_{\text{[C II]}} \) by assuming an initial mass function, with slope \( \alpha = 2.35 \) of between 0.1 and 100 \( M_\odot \), and using their \([\text{C II}] - \text{H}_\alpha \) relation determined from observations of a sample of Virgo galaxies, finding

\[
\text{SFR} = 1.73 \times 10^{-6} \times (L_{\text{[C II]}}/L_\odot)^{0.788} M_\odot \, \text{yr}^{-1}
\]

Assuming this relation holds for all galaxies at all redshifts, and that the source is not differentially lensed, we find SFR \( \lesssim 21 \, M_\odot \, \text{yr}^{-1} \). However, we note that Boselli et al. (2002) claim the relation only holds up to \( 10^{10.5} \, L_\odot \) and that the SFR is uncertain by up to a factor of 10, so we should not place too much confidence in the estimate. As a comparison, F97 find SFR \( \sim 36 \, M_\odot \, \text{yr}^{-1} \), based on near-infrared photometry and the star formation model by Bruzual & Charlot (1993). Hence the SFR implied by our \([\text{C II}] \) upper limit is loosely consistent with that inferred from the optical. However, given the approximations and assumptions made here, it is hard to draw any firm conclusions.

Luhman et al. (2003) find a deficit of \([\text{C II}] \) \( (L_{\text{[C II]}} < 10^{-3} \, L_{\text{FIR}}) \) in a sample of ULIRGs, and claim a negative correlation between \( L_{\text{[C II]}}/L_{\text{FIR}} \) and \( L_\nu(60 \, \mu\text{m})/L_\nu(100 \, \mu\text{m}) \) for galaxies of all types (see fig. 5 in Luhman et al. 2003). In order to compare our limit with sources in this plot, we calculate

\[
L_{\text{FIR}} = 1.26 \times 10^{42} \times [2.58 \, L_\nu(60 \, \mu\text{m}) + L_\nu(100 \, \mu\text{m})],
\]

with \( L_\nu \) evaluated at rest-frame wavelengths (assuming a modified blackbody) in W Hz\(^{-1}\) and \( L_{\text{FIR}} \) in W (see Helou et al. 1988). We find \( L_{\text{[C II]}}/L_{\text{FIR}} < 4.4 \times 10^{-3} \) and \( L_\nu(60 \, \mu\text{m})/L_\nu(100 \, \mu\text{m}) = 0.88 \), which is consistent with the published relation for normal star-forming galaxies. Nevertheless, firmer upper limits at similar levels for a sample of high-redshift star-forming galaxies will help to determine if there is a difference in the role of \([\text{C II}] \) in the early Universe.

Bolatto, Di Francesco & Willott (2004) recently reported an upper limit to \( L_{\text{[C II]}}/L_{\text{FIR}} \) in a \( z = 6.42 \) quasar, observed with the JCMT. They find \( L_{\text{[C II]}}/L_{\text{FIR}} < 5 \times 10^{-4} \). While this limit is lower than that published here, we note that a quasar is not a normal galaxy, and this source is \( \sim 200 \) brighter than ours, with \( L_{\text{bol}} \sim 10^{44} \, L_\odot \). Our measurement, because of lensing amplification, has allowed us to place a useful limit in a single high-redshift star-forming galaxy. Clearly, this is a difficult programme, and more sensitive measurements of both the \([\text{C II}] \) line emission and the FIR are required to significantly improve the constraint on \( L_{\text{[C II]}}/L_{\text{FIR}} \).
