How Much Does Employment Matter for Inequality in Canada and Elsewhere?

1. Introduction

The objective of this chapter is to compare income inequality in Canada with inequality in a selection of other advanced capitalist countries in the mid 1990s and to examine how much of the differences in income distribution between countries at that time may have been due to inter-country differences in employment. Most of the chapters in this volume focus on Canadian inequality, and analyze trends over time within Canada, but this chapter is motivated by the idea that international comparisons of inequality at a point in time offer a complementary, but somewhat different, way of setting our current level of inequality in context. As well, this chapter emphasizes the importance of differences in probability of paid employment and working time, because although there have been many comparisons of inequality, most papers about economic inequality, in this volume and elsewhere, do not pay much attention to differences in working time.[1] This omission of time should be surprising, since we are interested in the distribution of money income primarily because it is thought to be a good guide to the

distribution of economic well being. However, there is good reason to think that people care about both money income and the amount of time they have to work to earn that income. If money income differences are heavily influenced by differences in working time and if well being depends on both time and money, then comparisons of inequality with reference solely to differences in the distribution of money income may be misleading.

The working time issue is likely to be important for cross country comparisons because differences across countries are now large - and Europe and the USA seem to be following different trends. For example, ILO data[2] indicate that from 1980 to 2000, average actual working hours per adult (ages 15-64) rose by 234 hours in the USA to 1476 while falling by 170 hours in Germany, to 973. As Figure 1 illustrates, although Canada, France, Germany, Sweden, the United Kingdom and the United States all had average actual hours of paid work per adult which clustered in a fairly narrow interval in 1980, by 2000 the differential in actual hours of paid work was quite dramatic. When working hours change to this degree, it is reasonable to ask whether inequality might also be affected.

The measurement of working hours is, however, far from unproblematic.[3] As well, the correspondence between differences in working hours and differences in well being depends crucially on preferences – i.e. whether working hours are voluntarily chosen and whether preferences change over time or across countries. In comparing inequality across countries, it is also important to unpack the effects of differences in common entitlements to holiday and vacation time, differences in labour force participation and differences in individual hours of paid labour supply, conditional on participation. Differences between countries in average working hours per adult are determined both by differences in labour force participation

(sometimes called the "extensive margin" of labour supply) and by the distribution of hours among those with some employment (i.e. which has been called the "intensive margin" of labour supply). Because families in which nobody has a job are completely outside the paid labour market, the correlation between household members in probability of employment is particularly important for social exclusion – a dimension of inequality which increases the importance of examining international differences in household paid labour supply that are driven by differences in labour force participation.

Section 2 begins with a discussion of the problems which consideration of working time creates for the comparison of relative levels of inequality. It argues that differences between countries in the probability of participation in the paid labour market are responsible for much of the inter-country differences in average usual hours of work that have emerged in recent years. These differences are particularly marked for women, and there is some evidence that they are consistent with differing attitudes across countries to the relative importance of paid work and of child care and unpaid household production. Section 3 therefore proposes a methodology for assessing the extent to which differences in workforce participation may help to explain cross-country comparisons of inequality. Section 4 compares the actual distribution across individuals of disposable (after tax, after transfer) household money income, adjusted for family size, with the results of two simulations - one in which other nations' female workforce participation rates are held at the Canadian level and one in which their aggregate participation rates are fixed at the Canadian level. Section 5 concludes.

2. Inequality in Well-Being, Work and Money Income

In Figure 1, the countries plotted seem to group themselves into three broad types, with Canada, Sweden and the UK having very similar trends, intermediate between those observed in the USA and France/Germany. However, the trends in working time observed in Figure 1 do not just indicate that European labour markets were unable to generate as many jobs as the USA. If one adds to actual work hours the total number of unemployment hours (assuming that the desired weekly hours of the unemployed equal the actual weekly hours of the employed) the differences narrow somewhat, but the same basic picture emerges.

---Figure 1 inserted here---

The reason is that Figure 1 focuses on relative hours of employment. Hence, differences in employment rates matter more than differences in the unemployment rate, and when the unemployment rate is 10%, one could equally well say that 90% of the labour force is employed. Even though the unemployment rate in the USA (4%) in 2000 was less than that in, for example, France (10%), the difference in employment rates (96% of the labour force employed compared to 90%) is proportionately smaller. Hence, adjusting Figure 1 for unemployment does not change the basic picture. Adding together hours of actual work for pay and desired work (unemployment), one still gets the result that cross country differences are large – about 9 hours per week more for the average adult aged 15 to 64 in the USA compared to the average adult in France or Germany. What model might explain these differences?

In thinking about the relationship between time and money income, neo-classical labour supply theory often starts, in a one period model, with each individual maximizing a utility function, as in equation (1):

4

(1) $U = u(C, L)$

In this model, C represents consumption and L represents non-work time. The wage rate available in the paid labour market (w), the amount of non-labour income *(V)* and the total time (*T*) available [which has to be divided between hours of paid work (*H*) and non-work time (*L*)] are seen as the fundamentals which drive the time and money income constraints, as per equations (2) and (3).[4]

(2) $H + L = T$

(3) $C = wH + V.$

In this model, individuals are seen as choosing hours of work (*H*) to maximize utility (*U*). If it were really true that individuals could always obtain as many hours of work as they desired, at a constant real wage, then one could think of "full income" ($wT + V$) as the potential consumption available to each person. An individual's money income would, in this view, reflect partly that person's choice to consume part of their potential income in the form of material goods rather than as leisure time.

---Figure 2 inserted here---

The labour/leisure choice model has many deficiencies, but it can also be used to motivate a discussion of why consideration of working time might affect the measurement of inequality. Figure 2 is constructed to represent the possible impact on observed inequality of differing leisure preferences (i.e. a different "income effect" on leisure demand). Imagine that two societies (labeled A and B) are exactly alike in the income earning opportunities which they present to the rich and the poor - as represented by the budget lines *Y* and *Y'* in Figure 2.[5]

Imagine also that society A has more materialistic preferences, so that rich people in A maximize their utility at point *a'* (implying money income α') and poor people in A maximize their utility at point *a* (implying money income α). In less materialistic country B, which has different preferences but exactly the same choice set, rich people maximize utility at *b'* (hence have money income β.') and poor people maximize utility at *b* (with money income β). It is clear that money income differences are greater in A than in B [α'α > β'β]. Money income inequality is greater in A than in B, although labour market opportunities are the same, and the distribution of wealth is the same, because in A people prefer to take more of any given level of potential income in the form of cash income, rather than leisure (graphically, the expansion path of consumption with greater non-labour income has a steeper slope).

If this were a reasonable picture of the world, and if one were to assume that the USA is a more materialistic society, than other nations, then this model might help to explain the greater inequality of money income - and the longer average hours of work, and higher average money incomes - in the USA than in Europe. It would also fit with the general observation (in inequality and working time as in much else) that Canada is "In Between" France/Germany and America. [As well, this model predicts a lower variance of hours worked in the USA than in Europe, which is also true, for the population as a whole.] Its implication for the comparison of inequality across nations is that a correction for differences in tastes would narrow differences in the inequality of money income.

However, the trends in average actual hours of work per person of working age outlined in Figure 1 mingle the effects of trends in:

1. Common entitlements to leisure (i.e. paid public holidays, statutory paid vacations, etc.)

2. Individual participation in the paid workforce and

3. Actual hours of work of workers

It is not reasonable to expect that trends in all three components will be driven by the same processes or have the same impacts on inequality.

Common entitlements are determined by collective action, through the political process or in collective bargaining. By their nature, common entitlements tend to be an equalizing element in the distribution of economic well being, but although differences in such entitlements across nations can be significant,[6] their determinants are not well understood. The number of paid public holidays are, for example, determined by a set of political processes quite different from the determinants of individual decisions to enter the workforce and to work specific hours. It is clear from national employment legislation that the number of public holidays differs across countries – i.e. that individuals (as voters) in some countries prefer more or less of such a *common* entitlement from *collective* decision making, as opposed to choosing (as potential workers) *individually* optimal hours of work and leisure – but the standard economics model does not explain *why.*[7]

The model outlined in Figure 2 is a model of *individual* choice and it is also a model of the working time decisions *of workers* - i.e. labour supply at the intensive margin. Hence, the framework of Figure 2 is best suited to analysis of inequality *among workers* and is less well-suited to an examination of the influence on inequality *among all persons* of labour supply differences. In practice one of the most important sources of inter-country differences in labour

supply is differences in the proportion of adults with zero paid employment - i.e. differences at the "extensive margin."

As well, the simple labour/leisure choice model of Equation [1] requires one to assume away involuntary unemployment. Over time, total working hours within a country can change quite quickly, as the macro economy moves from boom to bust or vice versa. Variation in the quantity of labour demanded can impose involuntary changes in the amount of working time obtained by workers, and it is clear that constraints on available hours of work are most acutely experienced by the lower paid.[8] Since inequality in access to employment often interacts with inequality in hourly wages, measuring inequality solely in terms of a "full income / hourly wage" (which is not actually available to the involuntarily unemployed) seems likely to be misleading.

Osberg (2003) has argued that, particularly for prime age males, the distribution of usual hours of work *of workers* is very similar for Germany and the USA, except for the extreme lower tail of the distribution. Differences between these two countries in usual hours of work in the 1990s appear to be dominated by differences at the extensive margin of labour supply (especially among women and older men).

However, within Canada and the USA, the argument has also been made that the trend over time to greater inequality in household income is partly driven by the correlation of potential earnings of husbands and wives and the workforce entry of well educated women. In general, well educated women tend to marry well educated (potentially high income) men. If in the 1950s well educated wives tended to stay home, but in the 1990s tended to get paid jobs, then rising female employment might disproportionately swell the household income of upper income groups, thereby increasing measured inequality in household money income. If this were also an

8

explanation of cross country differences in measured inequality, one might think that if workforce participation elsewhere were to increase to North American levels, measured inequality in household money income in other countries would also rise - hence comparing inequality in the actual distribution of household money income "overstates" international differences in inequality.

---Table 1 inserted here—

Average actual working hours per adult can differ across countries because countries differ in both probability of working at all and in average working hours per worker. Table 1 therefore decomposes the difference in average actual hours of work in Canada and in the USA and the UK, Germany, France and Sweden due to employment rate differences, and hours per worker differences[9]. If we compare, for example, Canada and Germany, the difference of 212 hours of work per working age person per year can be decomposed into 118 hours ascribable to the difference in employment rates and 94 hours per year due to differences in working hours per employee.

In the Canada-Germany and Canada-France comparisons, it is the differences between countries in the proportion of the working age population who have any employment that is the larger part of the total hours differential, while the Canada-Sweden and Canada-USA comparisons are dominated by differences in average working hours per employee. (The Canada-UK over all differential is relatively small.) Evidently, although differences in employment probability are often very important, sometimes such differences are small – hence no single explanation of cross-country differences in working time per adult is likely to dominate for all cases.

9

Nevertheless, Freeman (2002) has suggested that differences in the "marketization" of production explains the US/Europe employment gap. He argues that the EU "produces relatively more goods and services through household production and less through the market than the US" (2002:2). Although he suggests this has implications for relative employment levels in the low skill service sector, and argues generally for the efficiency advantages of greater female labour force participation, he does not explain how or why such a large difference in marketization might have occurred. By leaving open the question of whether it is higher tax rates or differences in life style tastes that may be the crucial issue, he avoids judgment on whether differences in preferences explain inter-country differences in hours of work or whether the crucial issue is differences in the incentives which individuals (of broadly similar preferences) face.

By contrast, Garhammer (1999) does not hesitate to assert that nations can be characterized in terms of a specific "time culture", in which social institutions (such as the non-working weekend, or the holiday period surrounding Christmas and New Year's) and other social norms for time use are expressed in laws (such as working hour regulations, legal holidays, shop opening hours, etc.), collective agreements and individual habits (e.g. siestas). He argues that there is a distinctive European model of time culture in which the social enjoyment of time is highly prized and both "time prosperity" and material wealth are valued. He notes, for example, that "the majority of middle-aged Germans define the quality of life to which they personally aspire as "not being rushed." (Garhammer, 1999:69).

Typically, economists have been reluctant to appeal to differences in preferences to explain international differences in outcomes and have preferred to emphasize differences in incentives. Sociologists (such as Garhammer), on the other hand, have seen the description of

national differences in values as entirely legitimate (indeed, some would say, central to the discipline). These contrasting methodological approaches are quite important for the empirical analysis of the connection between working time and inequality. If one wants to compare the extent of economic inequality across countries and "standardize" the distribution of money income for differences in the probability of working, it might well be asked: "What thought experiment should be performed?"

If preferences are similar across countries, and if actual working time differences reflect primarily differences in incentive structure, then one could not have a change in hours of work without a change in incentives. In this case, one should run the thought experiment of a change in incentives, and examine its impact on both money incomes and time worked, because the structure of income distribution processes (i.e. the net income obtainable from work, after taxes and after any impact of earnings on transfer payments) would have to change if working hours were to change. In this case, one should model, for example, the impact of a similar income tax regime on both net earned income *and* working time.

However, if the sociologists are correct in asserting that differences in social values can be significant,[10] then it is plausible to ask how the distribution of income would change if preferences were similar, but the structure of incentives were unchanged. One might, for example, examine what the German distribution of income would look like, if Germans had the same preferences for material goods and non-work time as Canadians, but continued to face unchanged incentives in the labour market.

These contrasting methodological models are particularly relevant for analysis of the differences between countries in the extent of non-employment by women. If there are

differences between countries in such social norms as the proper locus of care for young children and the relative importance of paid work and family life in the definition of personal identity, then these cultural differences may be the primary determinants of differences in female workforce participation. Hakim (2000) is an example of the sociologists who have tried to explain the evolution of female attitudes to "home-centered" and "work-centered" models of identity. If national societies evolve differently in these dimensions, so that differences in preferences arise, then one can ask (without necessarily having to model differences in the income tax and social policy regimes) a question such as: "What would the German distribution of income look like if German women had similar attitudes to workforce participation as North American women, but faced the same labour market incentives as they now do?[11]

Many readers may already have some opinions on national differences in social attitudes, but one does not have to rely solely on casual observation. The World Values Survey and International Social Survey Program have, in repeated random samples, asked a comparable set of questions on social attitudes in advanced capitalist countries. Table 2 summarizes the results of some questions asked in the 1990-91 World Values Survey and 1998 ISSP survey rounds which were intended to probe social attitudes to "home-centred" and "work-centred" models of female identity.

In thinking about whether to enter the workforce, women must compare the positive attractions of possible greater intrinsic satisfactions of work for pay, compared to work in the home, with a possible negative - a potential cost in relationships, particularly with children. To the extent that families make joint decisions on these issues, male attitudes on these issues also matter. To track the perception of these issues, the WVS asked respondents whether they agreed

12

that "A working mother can establish just as warm and secure relationship with her children as a mother who does not work" and the ISSP asked whether respondents disagreed that "family life suffers when the woman has a full-time job." Although there is some evidence that younger Canadian women have more "non-traditional" attitudes than young American women, the similarity in Canadian and American responses is otherwise fairly high. There is some clear evidence in Table 2 of generational effects, but there are also strong national differences, even among the relatively young - e.g. the difference between younger German and North American women in the 1990-91 WVS was very large (twenty five percentage points). By 1998 there was less difference between Germany and the USA in attitudes to whether "family life suffers when the woman has a full-time job," but it was still significantly large.

Moreover, it is notable that on the straightforward role differentiation question of "do you agree, disagree … A husband's job is to earn the money, a wife's job is to look after the home and family," the percentage of younger Germans and North Americans who "disagree" or "strongly disagree" in 1998 differed by sixteen percentage points for women and twenty six percentage points for men. Evidently, there continue to be substantial differences between countries in how people answer questions which are designed to elicit the extent of support for a more traditional "home centered" model of female identity – a difference which may also help to explain differing definitions in Europe and North America of what it means to be a "feminist," and differing desired reforms to patriarchal institutions.

The responses summarized in Table 2 do not always conform to the stereotype of "More Liberated American Women." In 1998, for example, the percentage of American women under 35 who disagreed with role differentiation was appreciably less than in Canada, the UK, Sweden

or France. As well, it is very clear that male and female attitudes to gender roles differ - the twenty percentage point discordance between under 35 Swedish males and females in attitudes to husband and wife roles is especially notable! However, more often than not, the differences in attitudes between men and women within countries, in any given year, are small compared to the differences between countries. Attitudinal survey evidence is therefore consistent with the hypothesis of international differences in attitudes to participation in the paid workforce. However, the differences between "All ages" and "Under 35" attitudes can also be broadly taken as some evidence of convergence in attitudes - which can be seen as an indication that the thought experiment of "changing values" may not be entirely fanciful.

---Table 2 inserted here---

3. Statistical and Data Issues

3.1 Statistical

The USA is the largest nation in our sample, with the longest average working hours and the highest average money incomes, and is often used as the basis for comparisons (e.g. in the earlier version of this paper). However, for Canadians the most interesting thought experiment is a change in other countries' probability of paid employment, given the reward structure already in place there, to Canadian probabilities. To understand the impact of differing probabilities of employment on economic inequality this paper models the impact of a change (from the current country determinants to a Canadian model) in the probability of any employment in a year and, conditional on being employed at some point in the year, the expected net income associated with employment, for a person or household of given characteristics. The analysis proceeds in

14

two stages, first examining the implications of changed workforce participation by women and then considering men and women together.

In doing this, it considers separately the employment outcomes of single individuals and of persons in households. A probit model of the probability of employment at some point in the year in Canada is estimated for single workers, the results of which are presented in Appendix Table B1. Because there is a long tradition in labour economics (see, for example, Killingsworth, 1983) which recognizes that the labour supply decisions of husbands and wives living in households are interdependent, a multinomial logit model of household labour market decisions in Canada is estimated, conditional on the personal characteristics of both partners. For each household, four possible states are identified - [1] both husband and wife are employed at some point in the year; [2] husband employed, but wife never employed; [3] wife employed but husband never employed; [4] neither husband nor wife employed at any point in the year. The results are presented in Table B2.

The coefficients from these estimated equations are then used to answer the question: "what would the probability of employment at some point in the year be, for a person of given characteristics, if it was determined by the same probability process as in Canada?" For a single person, it is their own characteristics, plus the structural parameters summarized in Table B1, which determine an expected probability of some employment. For a person who is part of a household, the probability that they individually will be employed at some point in the year is the sum of the associated probabilities of household behaviour implied by Table B2 (e.g. a married woman's probability of employment is sum of [1] the expected probability that a household whose members have the same characteristics as her household will have both husband and wife

15

employed plus [2] the expected probability that a household whose members have the same characteristics as her household will be a "wife employed but husband not employed" household).

In these regressions, the influence of education on probability of employment is captured by a relative education variable which is calculated as the mean educational rank of a person of given educational credentials, in their ten year birth cohort. Countries differ significantly in the educational credentials they report, and equivalencies between credentials in different countries are sometimes problematic, but relative intra cohort educational rank is a concept that can be directly compared across countries. Individuals are classified as employed if they report any earnings or any weeks of work during the survey year.

To simulate the income distribution that could be expected in European countries if the workforce expanded to a Canadian level of participation, the expected probability of employment is calculated for each person and those outside the workforce are ranked by that probability. Table 3 reports the results obtained from a simulation of [1] changed behaviour by women and [2] when both male and female workforce participation is at Canadian levels. Assuming that a change (to Canadian values) in probability of employment would most affect those at the margin of labour market participation, this paper simulates this change in outcomes by adding to the workforce of the UK, Germany, France and Sweden, the non-employed who have the greatest relative probability of employment. Table 3 presumes that those individuals who already have some employment would continue in employment, and that if workforce participation were to rise to Canadian levels it would be the jobless individuals with highest expected probability of employment who would join the workforce.

In the USA, the probability of employment in 1997 was quite close to Canadian levels, but a bit higher. This implies that in simulating the income distribution corresponding to Canadian patterns of employment one has to *subtract* from the work force those individuals at the margin of employment (i.e. those employed persons with the *lowest* estimated probability of employment). However, because the difference between Canadian and US employment probabilities is not large, the simulated income distribution is in practice not much different from the actual US income distribution.

The impact, on the household distribution of disposable income, of those individuals joining the workforce will depend on the size of their additional individual earnings, the size of any associated change in the earnings of other household members, the impact of changed earnings (of both partners) on transfer payments and the change in taxes paid by both partners. To estimate the net income that the households containing additional workers would receive this paper uses the country specific OLS regressions of the form:

Net Disposable Income = F (age, age^2, relative education, family status, disability status, immigrant and labour market participation status, etc....)

The purpose of these regressions is to enable prediction (for the purpose of simulation). These regressions can be seen as a reduced form of the structural equations system which might predict the expected working hours of a person (or household) of given characteristics with specific expected wage(s), the earnings that those work hours would imply and the net income that a household with those earnings would receive after income tax is deducted and transfer

payments are adjusted. Both the structure of the tax/transfer system and the functional form of the labour supply function may be rather complex - hence their linear functional form should be seen as a first order approximation.[12]

In the simulated income distributions for each country reported in Table 3, this imputed net disposable income, of the households with simulated additions to the workforce, is added to the income of the other households whose labour market status is unchanged, and household equivalent income distribution statistics are calculated for the population as a whole. Note that this methodology will impose on all countries the Canadian pattern of correlation across spouses in employment, but leaves the country-specific income determination process of workers unchanged, under the maintained hypothesis that those households with unchanged workforce status do not change their net income.

The important issue for the accuracy of the simulations reported in Table 3 is whether the conditional expectation of disposable household income of workforce entrants - as calculated using the combination of their personal characteristics and the additional income associated with those characteristics implied by Tables B3 and B4 - is systematically biased to a degree that affects the summary statistics on income distribution reported in Table 3. Since there is always an element of judgement in the specification of the net income function (e.g in choice of functional form, or selection of right hand side variables), one way to check is to use an alternative plausible specification. Those alternatives that have been tried to date do not make very much difference.

3.2 Data

This paper uses Luxembourg Income Study micro data to present point estimates[13] of income distribution for the following economies: Canada (1997), France (1994), Germany (1994), Sweden (1995), United Kingdom (1995), and United States (1997). The focus is on "standardizing" the distribution of equivalent income among individuals to account for the impact of different national probabilities of employment, but the statistical starting point is the LIS definition of total household money income after tax and including transfers (disposable household income)[14] as the basis for calculation of the "equivalent income" of all working age individuals (and dependent children). All summary statistics refer to the distribution of equivalent disposable income among all national residents living in households with a head aged 64 or less, excluding only those economic families or unattached individuals who reported a zero or negative before tax money income. In all cases, where money figures are provided, local currency figures for income have been converted to year 2000 US dollars using the relevant country price deflator for consumer expenditure and OECD PPP estimates of purchasing power parity for consumption by households.

Estimates of the economic well-being of individuals within households depend heavily upon the assumptions made about the degree and pattern of economic sharing within households.[15] As well, estimates of the total well-being of the household depend upon the equivalence scale which is used to estimate the economies of scale in household consumption.[16] This paper uses the so-called LIS equivalence scale[17] in which the number of equivalent adults in each household is calculated as $N^{0.5}$. The LIS equivalence scale implies fairly large economies of scale in household consumption - the second person in a household counts as 0.41, the third

person receives a weight of 0.32 and a four person household is thought of as having the same relative level of consumption needs as two unattached individuals (i.e. with the same total money income, two adults living separately could live as well as each member of a four person family living together). This paper makes the assumption of equal sharing among all household members, and calculates the equivalent income of each household member as equal to the total money income of the household, divided by the number of equivalent adults in the household. This equivalent income is attributed to all household members, and the distribution of equivalent income across individuals is then calculated.

The most popular summary statistic of inequality is undoubtedly the Gini index, which is most sensitive to changes in the mid-range of the distribution. The Theil index is more sensitive to the bottom end, and also has the advantage of being additively decomposable (for further discussion see Jenkins (1991)). As an indicator of the extremes of the income distribution, we present also the "90/10 ratio" -- i.e. the ratio between the average incomes of the top 10% of persons and the average incomes of the bottom 10%. However, none of these measures reveal directly which part of the income distribution is changing - e.g. whether inequality is widening because the top end is pulling away from the middle or because the poor are falling behind the income growth of the middle of the income distribution. Since these issues are often of interest, Table 3 also presents the 90/50 and 50/10 ratios in order to better distinguish changes in the top and bottom of the income distribution. The percentages of the population with equivalent income greater than 150%, and less than 50%, of the median are also reported, as these statistics have also often been used as a guide to the degree of "polarization" in living standards.

In international comparisons, a frequently used relativistic conception of poverty draws the poverty line at one half the median national standard of living (Hagenaars, 1986, 1991) and since this paper calculates the equivalent income of each individual in each year, it defines the poverty line as one half the median equivalent income of all individuals[18] in that year. Two measures of poverty are presented - the poverty rate (percentage below half the median equivalent income) and the Sen-Shorrocks-Thon (SST) index of poverty intensity. Although the poverty rate is undoubtedly the most commonly used measure of poverty, it does not reflect the amount by which the incomes of the poor fall below the poverty line and it ignores the degree of inequality among the poor. As Osberg and Xu (2000) note, the SST index of poverty intensity is preferable on axiomatic grounds and can be decomposed into:

(3) $$P(Y; z) = (RATE)\ (GAP)\ (1+G(X)).$$

Where *RATE* is the poverty rate, *GAP* is the average poverty gap ratio among the poor and *G(X)* is the Gini index of poverty gap ratios among all people. Since *(1+G(X))* is in practice nearly constant over time and across countries, the SST index has the appealing property that it is roughly proportional to the expected poverty gap of a randomly selected individual (i.e. the crude probability of poverty multiplied by the expectation of the poverty gap, conditional on being poor).

4. Empirical Results

Table 3 presents the actual median and mean equivalent disposable income and the above set of income distribution summary statistics for Canada (1997), the USA (1997), UK (1995),

Germany (1994), Sweden (1995) and France (1994). For the latter five countries it also presents the results of simulating a Canadian level employment probability of women and of men and women combined. In these simulations, the impact on household disposable income of a change in probability of workforce participation is simulated - i.e. the simulations calculate the net benefit to household incomes of greater workforce participation *after* subtracting direct taxes and *after* any associated reduction in transfer payments.

In thinking about how changes in workforce participation would affect the level and distribution of economic well-being, one must recognize that household disposable income is only part of the picture. Typically, the impacts of greater workforce participation on GDP per capita exceed its impacts on average disposable personal earnings, because rising employment levels would partially benefit the budget balance of governments – enabling greater consumption of public services (which would have a distributional impact), even if tax rates were held constant. However, the focus here is narrower - the distribution of households' command over private resources (of time and money) - so this paper emphasizes the change in equivalent disposable household income.

It is no surprise that in all countries the results indicate that if additional workers entered the paid labour force, average and median equivalent income would rise. The effect is particularly marked in the UK when additional workforce participation by both men and women is considered - the simulations indicate that median equivalent disposable income might be expected to rise by about 13% and average income by 7%. As a number of authors have noted,[19] although the UK employment rate is in aggregate fairly high, that employment is concentrated among households. The percentage of working age households with zero employment income is

22

particularly high in UK data, so the impacts on average and median income of moving to Canadian workforce participation levels would be particularly large in the UK. Furthermore, since households without earnings are the poorest of the poor, bringing more households into the workforce would have large impacts on poverty.

The biggest changes in UK data therefore occur at the bottom of the income distribution. Bringing male and female workforce participation to Canadian levels could be expected to cut poverty intensity from 8.4 to 4.0 - and the poverty rate would fall from 15.6% to 10.6%. Polarization (as measured by the 90/10 ratio) would decline from a 10:1 ratio to about a 6.5:1 ratio, but most of that is happening because there is a compression at the bottom, since the 50/10 ratio shrinks by more than the 90/50 ratio. All these improvements in the money income of the less affluent would reduce measured inequality, and since the Theil index is more low end sensitive than the Gini, the fall in inequality as measured by the Theil (from .212 to .154) is proportionately much larger than the fall in the Gini (from .344 to .291). In general, bringing female workforce participation to Canadian levels produces about half the total change from bringing male and female participation to Canadian levels.

---Table 3 here---

Where there are smaller differences in workforce participation to begin with (e.g. the USA compared to Canada), the impacts on average and median incomes of changing to Canadian participation levels are correspondingly smaller. Table 4 shows the annual employment rate, by country.

---Table 4 here---

In the USA, for example, median income changes by only -$57 (about 0.2 %) if the US female workforce participation rate falls to the Canadian level, and by $270 (about 1%) if male and female employment levels are standardized. There is some change in poverty rate (an increase from 16.9% to 17.3%) when the impact of lower Canadian male workforce participation is simulated, but the impacts of simulated participation changes on the US income distribution are otherwise notably small – or non-existent. The broad conclusion from Table 3 is that very little of the US/Canada difference in income inequality can be explained by differences in workforce participation.

In Table 3 the Swedish results project a very small change in median and average equivalent income, and a tendency for income changes to be somewhat concentrated in the lower part of the income distribution. When both male and female participation is modelled at Canadian levels, poverty intensity falls significantly (from 6.6 to 5.3) and the bottom tail of the distribution compresses by considerably more than the top - the 90/50 hardly changes (shrinking from 2.0 to 1.9), while the 50/10 ratio declines from 2.8 to 2.5. Actual Canadian inequality starts from a considerably higher level than actual Swedish inequality, by any statistic one can choose, but the difference would be even larger if Canada and Sweden had similar patterns of workforce participation.

In the UK, and to a lesser extent in Sweden, the simulated changes in workforce participation reduce inequality most at the low end of the income distribution. In Germany and France, however, changes in family income from an increase in workforce participation to Canadian levels would be spread more evenly throughout the distribution. The simulations indicate a change in both countries in the Gini which is less than the drop in the Theil, but such

overall indices cannot indicate changes in different parts of the income distribution. In Table 3, the drop in the German population percentage with incomes above 150% of median income is considerably larger (3.1 percentage points) than the decline in the poverty rate (1.2 percentage points). In Germany and France, the simulated income distribution is more compressed than the actual income distribution - the simulated decline in the 50/10 ratio and the drop in the 90/50 ratio are of roughly the same size. Poverty intensity starts from a lower base in both countries than in Canada and although it falls in both (from 4.7 to 3.8 in Germany and from 3.6 to 2.6 in France), the decline is not nearly as dramatic as in the UK.

The continental European countries have, to begin with, an income distribution that is substantially more equal than that in the US, UK or Canada. Their actual poverty rates (among working age households) are in the 8% range, well below the poverty rate in Canada (13.5%), the UK (15.6%) and the USA (16.8%). Poverty intensity and the 50/10 ratio are similarly much lower in Germany, Sweden and France than in the Anglo-American countries, even before one considers the impact of added workforce participation. In continental Europe one can therefore argue that the income poverty and employment dimensions of social exclusion are, to begin with, much less closely aligned than in the Anglo-American countries. Hence, the simulations of rising workforce participation tend to show, for France and Germany, more of a compression of the distribution of income as a whole, rather than an effect which is concentrated in the lower tail.

Simulations of the impact of changing workforce participation on the income distribution can be a useful way of analyzing particular welfare state regimes. However, Table 3 also has two very general conclusions.

[1] In Europe, a higher employment rate would mean more equality of income distribution.

[2] In the mid 1990s, the differences between Canada and continental European countries in poverty would increase, if other countries had Canadian levels of employment.

The argument suggested by Figure 2 was that standardizing for labour/leisure preferences should have narrowed differences in measured inequality of income. Similarly, if it was the workforce entry of well educated women (married to high income men) in the 1980s and 1990s that was responsible (by disproportionately swelling the household income of upper income groups) for increasing measured inequality in household money income, then if workforce participation elsewhere were to increase to Canadian levels, measured inequality in household money income in other countries should rise. If either hypothesis were true, comparing inequality in the actual distribution of household money income "overstates" international differences in inequality.

However, the simulations of this paper indicate emphatically that neither is the case. In every country, rising workforce participation *reduces* inequality and poverty. If continental European countries had Canadian style determinants and levels of employment, differences in money income inequality and poverty would be *larger* - not smaller - than they are in actual data.

Figure 4, which examines working hours per household adult at different points in the distribution of income in 1994-95, may help to explain the simulation results. In Figure 4, individuals are ordered in each country by their equivalent individual disposable money income (after direct taxes and after transfers) and the average labour supply per household adult is calculated for each income decile. Panel A presents the average hours total. In Panel B each

26

country's decile average of working hours per household adult is expressed as a fraction of the corresponding Canadian decile. With the exception of the top income decile in the UK (which has the least work effort of the top decile of all countries examined),[20] there is a clear tendency for work hours to be higher in higher deciles of the income distribution - both absolutely and relative to Canada. At all points in the income distribution, Americans work more hours - but although the US incentive system has its greatest differentials in hourly rewards at the top of the income distribution, the differential in hours of work is significantly *smaller* at the top of the income distribution than at the bottom.

If non work time has utility, these data indicate that comparisons of money income inequality between the USA and other countries will underestimate differences in the inequality of utility. In the USA, the relatively poor work significantly harder for their greater relative poverty than they do in other countries. Cross country comparisons of inequality in money alone understate inequality differences in time and money.

---Figure 4 inserted here---

5. Implications and Conclusion

"Quality of life" or "Economic Well Being" may be concepts that are hard to define precisely, but most people would agree that they are influenced by both an individual's money income level and the discretionary time they have in which to enjoy it. Hence, if leisure time varies substantially, money income alone will be a misleading indicator of economic well being, which implies that international comparisons of money income inequality are potentially misleading indicators of the inequality of well being.

Trends in average actual working time are driven by collective decisions on common leisure entitlements, individual probabilities of having any employment and the average working hours of workers. The USA and Continental Europe (particularly France and Germany) have diverged sharply in these trends in recent years, while Canada is an intermediate case. This paper examined the extent to which differences in employment probability can explain international differences in income inequality. The basic conclusion is that international comparisons of the level of money income inequality likely <u>understate</u> the degree of differences in the inequality of economic well being. In the US, the relatively poor have to work quite a lot harder, and still end up with less income, than in European countries. In working time inequality as in money income inequality Canada is an intermediate case between Europe and the USA. Comparisons of inequality in money income have long indicated that Canadian inequality is greater than inequality in European nations[21]. However, since it is clearly worse to be poor in both time and money than to be poor in money income alone, this paper concludes that, compared to Europe, particularly Sweden and the UK, the distribution of economic well-being among Canadians is even more unequal than money income comparisons alone would indicate.

Appendix A

Measurement Issues

How many hours do people work in a given year? What methodology provides the best estimates?

To some extent, the answer depends on why one wants to know. Economists who are concerned with the study of factor productivity are interested in how many hours are worked, in total, at work sites and are uninterested in how those hours are distributed among particular workers. For this purpose, establishment based surveys may be appropriate, even if such surveys cannot reveal if the same worker has a number of simultaneous part time jobs, or how working hours are combined within households.

This paper is concerned with hours worked because it is part of the distribution of economic well being. Consequently, the aggregation of an individual's jobs into total hours and the correlation of hours within households is crucial and household based surveys are the appropriate instrument. However, as the OECD notes (2001:6), such surveys do not align exactly with administrative records in their aggregate totals.

As the OECD also notes (2001:5) "There are six main concepts of hours of work that are retained in different sources of labour statistics: actual hours, usual hours, contractual hours, legal hours, paid hours, hours offered (by employers)." It is the first two concepts which come closest to the labour supply concept used in economics. The "actual" hours of work concept highlighted in Figure 1 differs from "usual" hours of work since it allows for time not worked due to public holidays, paid vacation, illness,[22] etc. Using "actual" hours of work for a given respondent in a given week in a micro data survey exposes the data to both individual sampling

variability in such events as vacations and illnesses and full sample variability in such events as whether the survey was run during a week with a public holiday. As a consequence, the "usual hours" concept is commonly used in empirical work in labour economics - but one must be aware that international differences in average actual hours substantially exceed international differences in average usual hours (partly because countries differ in the number of paid public holidays and in mandatory vacation time entitlements).

Both usual and actual hours measures are assessed by the direct questioning of the respondents to household surveys (such the Current Population Survey in the US, or Canada's Labour Force Survey). It is this sort of data that the Luxembourg Income Study data base records, and which this paper uses. This methodology relies on the underlying assumption that the individual respondents to household surveys can provide unbiased estimates of their working time, subject to some ambiguity about the actual reporting of unpaid interruptions in working time (e.g. lunch or coffee breaks), an unavoidable amount of random reporting error and a tendency to "spiking" at standard working hour norms (such as 35 or 40 hours per week).

In the "time-use" field, Zick (2002) is one of those who have attacked this assumption, arguing that: "time diaries provide the most cost effective way of gathering valid and reliable time-use information." In time diary surveys, respondents are asked to record sequentially how they spend their time – ideally at least two 24-hour periods (one from a week day and another from a weekend) are recorded for each respondent. Because interviews must also be spaced over the year in order to capture any possible seasonal variations in time use, a time diary survey is a very expensive and time-intensive proposition, implying that time diary data have been infrequently gathered. Gershuny (2000, 249-253) has noted that when respondents fill in a time

use diary, their answers to the question "What did you do yesterday?" are a narrative which follows the time line through the day (e.g. "got up at 7, left the house at 8, got to work at 9, etc...."). This method has the advantages that it is the natural way people keep track of time and it necessarily imposes consistency in aggregate time use. Although it is then up to the researcher to calculate aggregate "work" or "leisure" hours, by summing across similar uses of time, Gershuny argues this is likely to be more accurate than the implicit process of categorization and aggregation that goes on when respondents are asked to add up in their heads the amount of time they spend "working for pay[23]" last week. The riposte, by defenders of the summary question methodology, is that time use diaries are typically constructed for one or two days - which imposes a sampling of days within the working week (or month) which introduces errors of its own.

How much might reporting error in paid labour supply matter? Zick (2002) comments "the few time-use reporting error studies that have been done to date suggest that data taken from stylized questions may be systematically less accurate than time-diary data and this reporting error may be related to individual and/or household characteristics that are often used as covariates in time use analyses." However, whether or not time diaries are more accurate, the core problem for researchers is the scarcity of data on working hours drawn from time use diaries, and the lack of linkage with comparable international data on the distribution of money income. Hence, this paper depends on the "stylized survey question" methodology.

[1] Employed is defined as those who had positive employee hours or weeks in the past twelve months or who were described as being self employed.

[2] Since education is reported differently across countries (e.g. the US reports highest level attained and the UK reports years of education), a relative measure of education is used. The population is divided into five age groups 18-24, 25-34, 35-44, 45-54, and 55-64 and ordered by education within each age cohort. Individuals are put into percentiles based on education level within each age cohort. Each individual is then assigned the average percentile for his/her education level.

	Appendix Table B2 Multinomial Logit[1] - Probability of Employment[2] in the Past Twelve Months Canada 1997-Married Males and Females		
	both not working vs both working	wife working, husband not working vs both working	husband working, wife not working vs both working

[1] There are four categories: 1. husband and wife have no employment; 2. the wife has employment but the husband has no employment; 3. the husband has employment but the wife does not 4. both employed
[2] Employed = employee hours >0 or weeks in past 12 months > 0 or self employed.
[3] See Note to Table 1

[first endnote, unnumbered]

Figure 1
**Annual Number of Hours Worked per Person Aged 15-64 [1]**

[1] = Average hours worked per employed person *(Employment / pop. age 15-64)
Canada and France 1999, 2000 and UK, US 2000 are extrapolations.

[1] Exceptions include: Johnson and Kuhn (2004), Jenkins and O'Leary (1996), Lee (2001), Doiron and Barrett (1996), Burtless (1993).

[2] International Labour Organization (2000) "KILM Hours of Work," see http://www.ilo.org/public/english/60empfor/polemp/kilm/kilm.htm.

[3] The distinction between "actual" and "usual" hours of work is particularly important for comparative analysis. The OECD Growth Project (see DSTI/EAS/IND/SWP(2001)16) and the University of Groningen and The Conference Board, GGDC Total Economy Database, 2002,(available at http://www.eco.rug.nl/ggdc) provide somewhat different estimates of actual hours of work per employee than the ILO. The Groningen estimates and the OECD numbers, together with the employment/population ratio data available from the Bureau of Labor Statistics, can be used to compute the same concept "average actual working hours per working age adult" as reported in Figure 1. There are differences in detail but the same basic picture emerges of widening differences in average actual work hours between the USA and France/Germany, with Canada, Sweden and the UK as intermediate cases – but see Appendix A for a fuller discussion of data issues.

[4] Clearly, this formulation assumes that work hours are available without quantity constraint at a constant real wage, without progressive taxation. Non-labour income (from capital or transfer payments) is assumed to be V, and any complications of human capital investment through on the job training are ignored.

[5] Implicitly, Figure 3 portrays a world where rich and poor differ in assets held (and therefore in non-labour income V), but not in human capital, hence the hourly wages implicit in both budget

46

constraints are identical. Inequality in both human and financial capital is a more realistic, but the same basic point remains.

[6]Using data from 1990, Bell and Freeman (1994:4) argue that: "Differences in weeks of vacation and holiday time translate into a 17% reduction in working time in Germany compared to a 9% reduction of work time in the United States, and therefore contribute .08 ln points to the annual hours gap between the two countries."

[7]See, however, Jenkins and Osberg (2005) for a model stressing the importance of co-ordination of leisure time – public holidays are all about simultaneous leisure time.

[8]Osberg and Phipps (1993:283) estimated, using the Labour Market Activity Survey of Statistics Canada that the Atkinson index of inequality (r=-0.5) of earned income in Canada would have fallen by about 30% if all Canadian workers had been able to obtain their desired weeks of work in 1986/87. In the interpretation of unemployment, Jahoda (1979), Kelvin and Jarrett (1985) and many other have also stressed that involuntary joblessness carries significant social and psychological costs.

[9]Define: Annual hours per person = H, hours per worker = h and the employment/population ratio = E, and use subscripts (c, o) to denote Canada and other countries. Then annual hours per person equals the product of hours per worker and the employment population ratio – i.e.

$$H_c = h_c E_c \text{ and } H_o = h_o E_o$$

Hence, $\quad H_c - H_o = h_c E_c - h_o E_o$

$$= h_c E_c + h_o E_c - h_o E_c - h_o E_o$$
$$= h_o (E_o - E_c) + E_c (h_c - h_o) ,$$

which are the two right hand columns in Table 1.

[10] Scott et al (1996) examine the evolution of gender-role attitudes in the UK, Germany and the USA. The difference in levels of support for what they call "pro-feminist" attitudes is striking.

[11]However, if Germans had different attitudes as workers, they might also have different attitudes as voters - and changes in social policy and labour market incentives might result. German tax/transfer incentives strongly favour the "Traditional" model of the family and child care by stay-at-home mothers [e.g. substantial financial incentives, for up to two years, are provided for women to remain at home and care for their children (Phipps:1994,1998)]. By contrast, American social policy has provided no such support for mothers to stay at home (indeed welfare policy has shifted strongly to encouraging/requiring the labour force participation of social assistance clients). This chapter is, therefore, best thought of as a *ceteris paribus* approximation in which labour market attitudes change, but voting behavior does not. As well, if labour supply shifted, the wage rate observed in labour markets would likely change, to a degree that would depend on the wage elasticity of labour demand. This chapter, however, holds constant both the current tax/transfer regimes and wage payment structures in each country.

[12]These regression results are available on request from the author and can be downloaded from earlier version of this paper available on the author's website.

[13]Although estimates of the confidence intervals surrounding these point estimates are not presented here, interested readers can find such estimates (for the population as a whole), as calculated using a bootstrap methodology, in Osberg and Xu (1997).

[14]Disposable income consists of the sum of gross wages and salaries, farm self-employment income, non-farm self-employment income, cash property income, sick pay, disability pay,

social retirement benefits, child or family allowances, unemployment compensation, maternity pay, military/veteran/war benefits, other social insurance, means-tested cash benefits, near cash benefits, private pensions, public sector pensions, alimony or child support, other regular private income, and other cash benefits; minus mandatory contributions for self employed, mandatory employee contribution, and income tax.

[15]Phipps and Burton (1995:194) have demonstrated the potential importance of inequality within the family - the same Canadian family income data is consistent with a child poverty rate (for two parent families) of as little as 5.9% if resources are equally shared or as much as 52.1% if resource sharing is minimal. However, this paper does not address these issues.

[16]Phipps and Garner (1994:13) argue that if one uses the same methodology for estimating equivalence scales, US and Canadian results are statistically and practically indistinguishable. Burkhauser, Smeeding, and Merz (1996) emphasize the differences in incidence and patterns of poverty implied by alternative equivalence scale methodologies in official use in Germany and the US and provide estimates of the sensitivity of the poverty rate in the US and Germany to alternative scale elasticities. See also Buhmann et al. (1988); Coulter, Cowell, and Jenkins (1992);

[17]Figini (1998, p. 2) notes that "OECD and other two-parameter equivalence scales empirically used show a similarity of results [in measurement of inequality] to one parameter equivalence scales with elasticity around 0.5."

[18]Measures of aggregate inequality (such as the Gini index) are dominated by the income distribution of the non-poor (the vast majority of the population). Hence, defining the poverty line in this way does not necessarily imply that poverty and aggregate inequality are closely related - see Osberg and Xu (1997).

[19]Osberg (2002a) notes that 20.4% of households of working age in the UK in 1995 LIS data have no reported employment - well above the rate in other countries. See also Gregg et al (1999).

[20]Given the rhetoric surrounding "incentives" and "initiative" during the Thatcher era, this is an intriguing finding.

[21] See, for example, Osberg (2003) or OECD (2005)

[22]The Luxembourg Employment Study data contains both actual and usual weekly hours and codes as possible reasons for any discrepancy: "Person has worked more than usual due to: variable hours (e.g. flexible working hours) 2. other reasons Person has worked less than usual due to: 3. bad weather 4. slack work for technical or economic reasons 5. labour dispute 6. education or training 7. variable hours (e.g. flexible working hours) 8. own illness, injury or temporary disability 9. maternity leave 10. special leave for personal or family reasons 11. annual holidays 12. bank holidays 13. start of/change in job during reference week 14. end of job without taking up a new one during reference week 15. other reasons" (see page 4 at http://www.lisproject.org/les/varvalue.pdf).

[23] As a check, the readers of this article might want to think how they personally would respond to the question "What is the usual number of hours per week you spend working for pay?"
