DATE: July 14, 2011

AUTHOR: Tyler Reddy

TITLE: Structure, Flexibility, And Overall Motion Of Transmembrane Peptides

Studied By NMR Spectroscopy And Molecular Dynamics Simulations

DEPARTMENT OR SCHOOL: Department of Biochemistry & Molecular Biology DEGREE: PhD CONVOCATION: October YEAR: 2011

Permission is herewith granted to Dalhousie University to circulate and to have copied for non-commercial purposes, at its discretion, the above title upon the request of individuals or institutions. I understand that my thesis will be electronically available to the public.

The author reserves other publication rights, and neither the thesis nor extensive extracts from it may be printed or otherwise reproduced without the author's written permission.

The author attests that permission has been obtained for the use of any copyrighted material appearing in the thesis (other than the brief excerpts requiring only proper acknowledgement in scholarly writing), and that all such use is clearly acknowledged.

Abstract

Nuclear magnetic resonance (NMR) spectroscopy was used to determine the structure of transmembrane (TM) segment IX of the Na⁺/H⁺ exchanger isoform 1 (NHE1) in dodecylphosphocholine micelles. Studying isolated TM segments in this fashion constitutes a well-established "divide and conquer" approach to the study of membrane proteins, which are often extremely difficult to produce, purify, and reconstitute in full-length polytopic form. A similar approach was combined with NMR spin relaxation experiments to determine the peptide backbone flexibility of NHE1 TM VII. The combined NMR structural and dynamics studies are consistent with an important role for TM segment flexibility in the function of NHE1, a protein involved in apoptosis and myocardial disease. The study of the rhomboid protease system is also described from two perspectives: 1) I attempted to produce several TM constructs of the substrate spitz or a related construct and the production and purification are described in detail; and 2) I present coarse-grained molecular dynamics simulation results for the E. coli rhomboid ecGlpG and a spitz TM construct. Spitz appears to preferrentially associate with rhomboid near TMs 1 and 3 rather than the proposed substrate gate at TM 5. The two proteins primarily interact at the termini of helices rather than within the hydrocarbon core of the bilayer. Finally, I present a detailed analysis of coarse-grained molecular dynamics simulations of the fibroblast growth factor receptor 3 TM domain dimerization. Specifically, algorithms are described for analyzing critical features of wild-type and G380R mutant constructs. The G380R mutation is the cause of achodroplasia, the most common form of human dwarfism. The results suggest that the proximity of a residue to the dimer interface may impact the severity of the mutant phenotype. Strikingly, heterodimer and mutant homodimer constructs exhibit a secondary dimer interface which may explain the increased signaling activity previously reported for the G380R mutation—the helices may rotate with the introduction of G380R. The unifying theme of this work is the 'study of membrane proteins' using complementary techniques from structural biology and computational biochemistry.

Acknowledgements

My PhD project supervisor, Dr. Jan K. Rainey, provided exceptional guidance for the duration of my thesis work in his laboratory. Jan's open-door policy, career advice, and willingness to send trainees to training workshops and conferences is commendable. Jan also encouraged my application for a Natural Sciences and Engineering Research Council of Canada (NSERC) Michael Smith Foreign Study Supplement. This scholarship allowed me to pursue an interest in learning to perform and analyze molecular dynamics simulations at one of the world-leading laboratories in this field at the University of Oxford. It strikes me as unlikely that most graduate supervisors would encourage their trainees to explore working for another group for six months, and this was one of the most important experiences of my PhD work. I am very thankful to Jan for supporting (or at least tolerating!) my transition from experimental to computational biochemistry.

Substantial collaborations include work with Drs. Brian D. Sykes, Larry Fliegel and Joanne Lemieux at the University of Alberta, who have all been very kind and helpful. A number of current and former members of the Rainey laboratory at Dalhousie University provided assistance for parts of my project: Bruce Stewart, Caitlin Reid, David N. Langelaan, Marie-Laurence Tremblay, Aaron Banks, Kyungsoo Shin, Lesley Seto, and Jonathan Melong. Drs. Stephen Bearne (also my honours project supervisor), David Waisman, Barbara Karten, Carmichael Wallace, and Andrew Roger kindly provided access to crucial experimental instruments. I thank Dr. Edward

d'Auvergne for extensive discussion of NMR spin relaxation calculations and Dr. Leo Spyracopolous for providing Mathematica notebooks and suggestions for relaxation analysis. Jason Moses and Marc Genest were involved in peptide synthesis and purification for an important part of my project. Dr. Mostafa Hatam (AAPPTec) and Wayne Kottkamp (JASCO) provided excellent technical advice.

I've also had the luxury of working in the laboratory of Dr. Mark S. P. Sansom at the University of Oxford. Mark was very kind for the duration of my stay and encouraged my interest in returning for post-doctoral studies. I'd like to thank a number of current and former members of the Structural Bioinformatics & Computational Biochemistry Unit (SBCB) for helpful discussions and suggestions: Dr. Philip W. Fowler, Dr. Oliver Beckstein, Dr. Phillip J. Stansfeld, Antreas Kalli, Khairul Adb Halim, and Dave Marshall.

I would also like to thank Dr. Boris Kablar, who supervised my early years of undergraduate summer research and encouraged a career in research. Much of my practical scientific training came from work in his group at the Anatomy & Neurobiology Department at Dalhousie University.

I have been supported by an NSERC Canada Graduate Scholarship (CGS) D, a Killam Honourary Predoctoral Fellowship, an NSERC CGS M, a Nova Scotia Health Research Foundation (NSHRF) Student Research Capacity Award, and Dalhousie University. I also acknowledge support from the Department of Biochemistry & Molecular Biology at Dalhousie University, and the SBCB and Department of Biochemistry at the University of Oxford. Parts of the reserach were supported by grants from Canadian Institutes of Health Research (CIHR), NSHRF, the E. Gordon Young Endowment Fund, NSERC, and the Protein Engineering Network of Centres of Excellence.

A 500 MHz spectrometer at the Nuclear Magnetic Resonance Research Resource (NMR-3; Halifax, NS) was used for several experiments with expert assistance from

Drs. Michael Lumsden and Kathy Robertson, and more recently a 700 MHz spectrometer at the Biomolecular Magnetic Resonance Facility (BMRF—National Research Council Canada; Halifax, NS) has been employed. Many NMR experiments were performed at the Canadian National High Field NMR Centre (NANUC; Edmonton, AB) on an 800 MHz spectrometer with assistance from Dr. Ryan McKay. Operation of NANUC is funded by CIHR, NSERC, and the University of Alberta. Molecular dynamics simulations were performed using resources provided at the SBCB (Oxford, U.K.) and by ACEnet, the regional high performance computing consortium for universities in Atlantic Canada. ACEnet is funded by the Canada Foundation for Innovation (CFI), the Atlantic Canada Opportunities Agency (ACOA), and the provinces of Newfoundland & Labrador, Nova Scotia, and New Brunswick.

Chapter 1

Introduction

If there is a single unifying theme to this body of work it would have to be the 'study of membrane proteins.' Chapter 2 (page 3) concerns the nuclear magnetic resonance (NMR) spectroscopic based elucidation of the structure of the ninth transmembrane (TM) segment of the Na⁺/H⁺ exchanger isoform 1 (NHE1) in a membrane-mimetic medium. Studying an isolated TM segment is a well-established strategy to improve tractability by overcoming the difficulty of producing, purifying, and reconstituting polytopic membrane proteins. This "divide and conquer" approach (5) was also used to study the seventh TM segment of NHE1 as detailed in Chapter 3 (page 27), but in this case I examined the ps-ns and μ s-ms timescale dynamics of peptide backbone flexibility in a membrane-mimetic environment using NMR spin relaxation experiments. I employed the common Lipari-Szabo model-free analysis (6, 7) as well as reduced spectral density mapping (8, 9) to gain insight into the dynamics of the system. The following two chapters are based on three of my published manuscripts (1, 2, 3).

In Chapter 4 (page 58), I switch to the study of the rhomboid protease system. However, in keeping with the above theme, rhomboids are polytopic membrane proteins which cleave single-pass TM proteins within the phospholipid bilayer in prokary-otes and eukaryotes (10). My specific objective was the production, purification, and NMR-based structural study of a construct of the TM portion of the *Drosophila*

spitz peptide—part of the natural substrate of Rhomboid-1. This is a labwork-heavy chapter as it was extremely challenging to produce and purify a number of different spitz-based or related constructs.

Although NMR-based structural and dynamics studies of membrane proteins can provide a lot of valuable information, one missing piece of information is how the peptide or protein structures move (on a larger scale) within phospholipid bilayers and interact with other proteins. I have employed coarse-grained molecular dynamics (CG-MD) simulations to study protein-lipid and protein-protein interactions for two membrane protein systems. In chapter 5 (page 108), the dimerization of the fibroblast growth factor receptor 3 (FGFR3) TM domain (of particular interest because of its role in human achondroplasia (*i.e.*, reference (11))) is studied in detail using CG-MD. This chapter integrates a detailed discussion of analytical algorithms used to parse crucial information from wild-type homodimer, heterodimer, and mutant homodimer FGFR3 simulation trajectories. Chapter 6 (page 191) outlines preliminary CG-MD simulation results for a system consisting of a rhomboid protease construct and a spitz TMD construct in a phospholipid bilayer.

This work therefore employs complementary techniques from structural biology and computational biochemistry to probe a number of membrane protein systems. The self-contained introductions in subsequent chapters will introduce the specific systems and techniques in detail, and the appendices contain documented source code and additional results.

Chapter 2

NMR Structure Of NHE1 TM IX (Based On Published Manuscript (1))

2.1 Introduction

The human Na⁺/H⁺ exchanger isoform 1 (NHE1) is involved in a number of important biological processes. These include regulation of intracellular pH, cell growth and differentiation, cell migration, and regulation of sodium fluxes (reviewed in (12)). There is also substantial interest in NHE1 because of its established role in the myocardial damage that occurs during ischemia, reperfusion and a possible role in mediating cardiac hypertrophy. Despite the motivations for studying NHE1, there are no high-resolution atomic structures of the protein available in the literature.

NHE1 is a ubiquitously expressed plasma membrane protein, and based on functional and phylogenetic analysis it is proposed to include 12 N-terminal TM segments and a C-terminal regulatory domain (13, 14). Our objective was to use an NMR spectroscopy-based approach to obtain high-resolution atomic structural information on NHE1. In light of the poor tractability of the polytopic TM protein, we opted to use the "divide and conquer" approach to membrane protein structure determination (reviewed in (5)). This method consists of producing isolated TM segments, solving their structures in membrane-mimetic environments, and then recombining the

individual TM segment structures to get an overall picture of the polytopic configuration. The NMR structures of a number of NHE1 TM peptide segments have been solved as part of a "divide and conquer" strategy, and I have described the details of these structures (along with several successful examples of the "divide and conquer" approach) in the published manuscript (1).

We specifically chose to study NHE1 TM segment IX (residues 339-363 in the Wakabayashi topology (13)) for three reasons: 1) TM IX is important in mediating sensitivity to NHE1 antagonists (15); 2) Alteration of H349 in TM IX reduced exchanger sensitivity to amiloride (inhibitor) compounds (16); 3) Site-directed mutagenesis is consistent with additional importance for TM IX in NHE function and drug sensitivity (17, 18).

My work on a 31-residue synthetic peptide construct of NHE1 TM IX employed circular dichroism (CD) spectropolarimetry and NMR spectroscopy for structural characterization. In parallel, our collaborators in the laboratory of Dr. Fliegel (University of Alberta) conducted a cysteine-scanning mutagenesis study to determine the importance of each residue in TM IX for full-length cysteineless NHE1 (cNHE1) activity. The latter functional methods and results are detailed in the manuscript (1), while the structural results are described below with integration of crucial functional results where appropriate.

2.2 Materials And Methods

2.2.1 Materials

Deuterated dodecylphosphocholine (DPC) was purchased from C/D/N isotopes (Pointe-Claire, Quebec, Canada).

2.2.2 Peptide Synthesis And Purification

A (> 95 %) purified 31-residue peptide construct of NHE1 TM IX containing

cationic caps at the N- and C- termini (KSYMAYLSAELFHLSGIMALIASGVVMRPKK; acetylcapped N-terminus, amide-capped C-terminus) was purchased from GL Biochem (Shanghai, China). Purity was assessed by high performance liquid chromatography (HPLC) and identity was confirmed by matrix-assisted laser desorption ionization (MALDI) mass spectrometry and sequential assignment of NMR spectra.

2.2.3 NMR Spectroscopy And Structure Calculations

An NMR sample was prepared by dissolving 0.9 ± 0.1 mM peptide (concentration estimated from ¹H one-dimensional NMR spectrum integrations relative to the internal standard using assigned resonances) in 95% H₂O, 5% D₂O solution containing ~ 75 mM deuterated DPC and 0.25 mM (d_6)-2,2-dimethyl-2-silapentane-5-sulfonic acid (DSS) for chemical shift referencing. The experiments were conducted at 30 °C on the sample with pH 5.05 (without accounting for deuterium isotope effects). One-dimensional ¹H, natural abundance gradient-enhanced ¹H-¹³C HSQC (heteronuclear single quantum correlation), two-dimensional ¹H-¹H TOCSY (total correlation spectroscopy) (60-ms mix; decoupling in the presence of scalar interactions spin lock), and NOESY (nuclear Overhauser effect spectroscopy) (225-ms mix) experiments were acquired on the Canadian National High Field NMR Centre Varian INOVA 800-MHz spectrometer. All experiments were used as configured within the Varian BioPack software package. Spectra were processed using NMRPipe (19) and analyzed using Sparky 3 (20). All spectral assignments were carried out by manual peak picking in Sparky, and resonance assignments have been deposited in the BioMagResBank (code 15747).

Structure calculations were performed in the Python scripting interface of XPLOR-NIH version 2.18 (21) using NOE restraints from the assigned spectrum. Peak volumes were independently calculated using Gaussian and Lorentzian fit Sparky algorithms, with no allowed peak center motion. Those peaks that were not assigned a volume or were assigned a negative volume by the algorithm (~27.5%) were either manu-

ally assigned a summed signal intensity as defined by a user-specified region or fit by Sparky algorithm after contour adjustment. Peak volumes were empirically calibrated to distance ranges of 0-5.0, 1.8-5.0, and 1.8-6.0 Å; the Lorentzian fit volumes were more conservative and used for subsequent analysis. Restraints were divided into bin ranges corresponding to strong (1.8-2.8 Å), medium (1.8-4.0 Å), weak (1.8-5.0 Å), and very weak (1.8-6.0 Å) contacts. Ambiguous assignments and NOE potential scaling were handled as described previously (22). Following 21 rounds of structural refinement by simulated annealing, an additional 6 rounds were performed with dihedral angle potential scaling factors of 5, 50, 100, 100, 50, and 25. Simulated annealing parameters were similar to those described previously (22), but with 15000 cooling steps.

A single extended polypeptide was generated and subjected to simulated annealing for each round. To handle the families of 100 structures generated per round an in-house tcl/tk script (freely available upon request from J. Rainey) was used; the script allowed for assessment of violations and iterative refinement of NOE restraints. Refinement gradually increased in stringency, initially violations > 0.5 Å in > 50 % of structures were lengthened, but subsequently violations > 0.1 Å in > 25 % of structures were modified. After 21 cycles of simulated annealing and NOE refinement, calculated XPLOR-NIH structure energies contained minimal contributions from NOE violations, and magnitudes of all observed violations were minimal. All NOE restraints were satisfied without pruning. Six further cycles of simulated annealing were carried out with incorporation of dihedral angle restraints as described above. The lowest 40 energy structures in the final ensemble of 100 were retained for further analysis. The final sets of restraints have been deposited in the Protein Data Bank with this ensemble of 40 structures (Research Collaboratory for Structural Bioinformatics Protein Data Bank code 2k3c).

2.2.4 CD Spectroscopy And Analysis

Samples for CD spectroscopy were diluted from the previously described NMR sample to obtain samples of ~10 μ M peptide, ~3 mM deuterated DPC, and the unbuffered pH was adjusted to ~4.8 in a chloride-free solution. Nine replicate measurements were collected over 3 separate days on a Jasco J-810 spectropolarimeter (Easton, MD) at 30 °C in a 0.1-cm path length (Hellma, Müllheim, Germany) water-jacketed cell (20 nm/min scan rate). Data were collected in a wavelength range of 260-180 nm but the signal to noise ratio was considered reasonable only at a detector (photomultiplier tube) voltage under 700 V (based on previous instrumental observation). Averaged data were analyzed by several algorithms (23) using the DICHROWEB interface (24, 25).

2.3 Results

2.3.1 Peptide Design And Conditions For NMR Spectroscopy

The synthetic peptide contains three lysine residues, one at the N terminus and two at the C terminus, which are not present in the endogenous sequence of the NHE1 protein. Cationic residues at the termini of peptides have been shown to facilitate both peptide purification and maintenance of transbilayer orientation (26). For convenience, the lysine residues are numbered relative to the endogenous sequence. All structural studies were conducted on the 31-residue peptide produced by chemical synthesis with no isotope labels.

TM peptide solubility is often problematic, and while NHE1 TM IV was soluble in organic solvents (27), TM VII was substantially more soluble in DPC micelles (22). We opted to use DPC micelles for solubilization of TM IX because this system is proposed to be a more appropriate membrane-mimetic than organic solvents (28). Sample components were 0.9 ± 0.1 mM peptide, ~75 mM deuterated DPC, and 0.25 mM DSS in 95% H₂O, 5% D₂O adjusted to pH ~5.05 and studied at 30 °C. This

temperature provided good NMR spectral characteristics, prevented precipitation for extended periods of spectroscopic study, and allows for use of the cryogenically cooled triple-resonance probe on the 800-MHz Canadian National High Field NMR Centre spectrometer. This combination of factors allowed determination of the structure of the TM IX segment in DPC micelles.

2.3.2 Resonance Assignment And Structure Calculation

Sequential chemical shift assignments were carried out using two-dimensional TOCSY, natural abundance ¹H-¹³C HSQC, and NOESY experiments (22, 29) (Figure 2.1 on page 17). Acquisition of a natural abundance ¹H-¹⁵N HSQC data set was not feasible because of low signal-to-noise arising from the tumbling rate of the peptide-containing micelles. Resonance assignments for ¹H were complete except for Met-H $^{\epsilon}$ and Phe-H $^{\delta}$. In some cases there were missing or ambiguous 13 C assignments $\text{for Tyr-C}^{\alpha}, \ \text{Met-C}^{\alpha}/\text{C}^{\epsilon}, \ \text{Leu-C}^{\beta}/\text{C}^{\gamma}/\text{C}^{\delta 1}, \ \text{Ser-C}^{\alpha}/\text{C}^{\beta}, \ \text{Glu-C}^{\alpha}, \ \text{Phe-C}^{\beta}, \ \text{His-C}^{\alpha}/\text{C}^{\delta 2}, \\ \text{Ser-C}^{\alpha}/\text{C}^{\beta}, \ \text{Clu-C}^{\alpha}, \ \text{Clu-C}^{\alpha}, \ \text{Clu-C}^{\beta}, \ \text{Clu-C}^{\alpha}, \ \text{Clu-C}^{\beta}, \ \text{Clu-C}^{\beta},$ and Lys- C^{γ} . Assessment of unambiguous assignments was made as described previously (22). The latter approach involves the use of ambiguous assignments in structure calculations where unambiguous assignments were not possible. A total of 1231 unique NOE restraints (Table 2.1 on page 25) were used for calculation of the TM IX structure. These are summarized graphically in terms of the standard connectivities examined for secondary structure characterization (Figure 2.2 on page 18) and in terms of the number of unique restraints per residue (Figure 2.3 on page 18). A progressive energy minimization of calculated NMR structural ensembles with each round of refinement is detailed in Figure 2.4 on page 19.

2.3.3 Structural Analysis Of TM IX Peptide

An ensemble of the 40 lowest energy structures from 100 calculated peptide structures was obtained that satisfy the 1231 observed unique NOE restraints with minimal violations (Table 2.1 on page 25). Dihedral angle restraints ($\phi = -60 \pm 30$;

 $\psi = -40 \pm 40$) consistent with α -helical structure were imposed over residues M340-S344 and I353-S359, based on the seconday chemical shift analysis (Figure 2.5 on page 20). The dihedral restraints resulted in a significant but reasonable (~17 %) inflation in total energy relative to an ensemble restrained only by NOEs (Table 2.1 and Figure 2.4).

A 9-replicate averaged CD spectrum was analyzed using the DICHROWEB (24, 25) interface by applying several secondary structure deconvolution algorithms (results summarized in Table 2.2 on page 26). A 190 nm low-wavelength cutoff was used for meaningful signals as detailed in section 2.2.4. The normalized standard deviation parameter was used to filter those algorithms that did not produce a good fit to the data (normalized rmsd > 0.2) (30). The calculated average secondary structure contributions are 26 ± 5 % helix, 31 ± 6 % sheet, 16 ± 4 % turn, and 29 ± 10 % random (Table 2.2). In light of the relatively high average deviations across algorithms, a qualitative inspection of the CD spectra is relevant (Figure 2.6 on page 21). To reflect the 12/31 (~ 39 %) helical residues predicted based on NMR dihedral restraints, a (theoretical) 39 % helix CD spectrum from 200 to 240 nm was generated by K2D (23). The experimental curves are qualitatively consistent with a strong helical contribution.

Superposition of all members of the ensemble over the full length of the peptide was not possible. However, based on rmsd analysis as detailed in (29), K337-L350 and G352-V362 were respective N- and C-terminal segments consistent with a relatively invariant structural fold (Figure 2.7 on page 22). The intervening S351 serves as a pivot point between the N- and C-terminal portions of the peptide, although its dihedral angles across the ensemble of structures are well clustered (Figure 2.8 on page 23), and its dihedral angle order parameters are close to unity, but in close proximity to a flexible region (Figure 2.9 on page 24). Residues assigned to the two helical segments were also well clustered by dihedral angle (Figure 2.8). While the

penultimate C-terminal K residue was surprisingly well-clustered by dihedral angle, M363 (also near the C-terminus) had a large dispersion of backbone dihedral angles over the ensemble (Figure 2.8).

2.3.4 Structural Superposition Of TM IX

Peptide segments between 4 and 19 residues long were iteratively superimposed to provide a minimum rmsd relative to the backbone of the lowest energy structure (Figure 2.7 on page 22). Those superpositions producing the largest contiguous segments of residues with rmsd values < 1.0 were additionally filtered based on average rmsd across the entire segment. The following permutations were assessed: N-terminal segments between residues 337-342 and 345-354 and C-terminal segments between residues 349-354 and 357-367 were superimposed by the method of Kabsch (31) as implemented in the LSQKAB software of the CCP4 suite (32). K337-L350 and G352-V362 were the respective N- and C-terminal regions with rmsd values most consistent with a fixed region of structure (Figure 2.7 on page 22). The dihedral angle order parameter (Figure 2.9) was consistent with a region of structural flexibility (i.e., a pivot point at S351) between the determined segments.

2.4 Discussion

2.4.1 Structural Analysis Of TM IX

Where the full-length structure of proteins is available, studies have shown that isolated TM segments both reflect the structure of intact proteins and often retain their functional characteristics. Specific examples include bacteriorhodopsin (33, 34), rhodopsin (35), the cystic fibrosis TM conductance regulator (36, 37), and the fungal G-protein-coupled receptor Ste2p (38). Stabilization of the physiological structure of a TM segment may be solvent-dependent as observed previously with bacteriorhodopsin (33, 34), and TM IV (27) and TM VII (22) of NHE1. For this reason, we solubilized

the 31-residue synthetic TM IX peptide in membrane-mimetic DPC micelles, a system that has been well established (39, 40). We found that the structure of the TM IX peptide in DPC micelles is an interrupted helix with a sharp, although potentially flexible, bend immediately N-terminal to S351 (Figure 2.7 on page 22). This bend results in a kinked, "L"-shaped structure retained across amino acids 338-365. The relative position for the N- and C-terminal superposition segments around the S351 pivot is slightly variable across the ensemble. We have previously reported a similar observation for NHE1 TM VII in DPC micelles, which was also determined by NMR spectroscopy to be an interrupted helix, although with more variability in the angle of the bend between converged segments (22). The residues involved in the kink of TM VII were observed to be functionally critical residues. Similarly, it has been reported that helix IV of NHE1 is kinked at functionally important amino acids (27). The actual degree of flexibility in the context of the full-length protein would depend on constraining interactions arising from other helices, from the surrounding lipid bilayer, and through homodimer contacts (41). Kinked helices are thought to play an important role in transport function for the prokaryotic Na⁺/H⁺ exchanger NhaA (42), and the trend of studies on TM segments of NHE1 shows residues appearing at kinked locations that are functionally critical.

There are two different membrane-spanning topologies for the NHE1 protein proposed in the literature. The first, by Wakabayashi and co-workers (13), is based on cysteine-scanning accessibility analysis and led to the present widely used model with TM IX including amino acids 338-360. More recently a model was developed based on fold recognition using the *E. coli* NhaA crystal structure as a template for phylogenetic analysis and homology modeling (14). In this model, amino acids 338-360 of TM IX correspond to part of TM VII, a subsequent extracellular loop, and all of TM VIII. Landau *et al.* (14) suggest that the previously described TM IX is an artifact of the window size used for hydropathy analysis. However, the TM VIII arising from

their model has a membrane-spanning length of ~ 19 Å, which is short for a eukaryotic membrane (43).

2.4.2 Structure-Function Correlation

In addition to the structural studies described above, a complementary set of functional experiments on full-length cNHE1 in living cells were conducted by researchers in the laboratory of our collaborator (Dr. Fliegel, University of Alberta), and the results are detailed in the published manuscript (1). In all cases, they were able to express an intact Na⁺/H⁺ exchanger protein. However, five of the mutants had decreased NHE1 protein activity. For L343 and S351 this was due, at least in part, to decreased expression and improper targeting. For Y339, I353, A355, and V361, significant defects in protein function were introduced by mutation. The E346, I353, and V361 side chains face the opposite direction of Y339, S351 and A355 side chains in our structure (Figure 2.7). This would seem to conflict with their importance in function; however, Landau et al. (14) suggested that S351 faces the lipid bilayer despite its functional importance and that it can rotate by 180° to face the pore for ion coordination. If true, the segment may sometimes face the pore and sometimes the lipid bilayer.

Only two mutants, E346C and S351C, were strongly inhibited by reaction with MTSET ((2-(trimethylammonium) ethyl)methanethiosulfonate) (a positively charged sulfhydryl-reactive reagent), and no mutants were inhibited by MTSES ((2-sulfonatoethyl) methanethiosulfonate) (a negatively charged sulfhydrl-reactive reagent). The most likely explanation for their reactivity with MTSET is an interaction at a site that lines and blocks the ion translocation pore (44). There were minor inhibitory effects of MTSET on the adjacent amino acids A345 and L350 (1). Their mutation could cause a minor perturbation of the structure of TM IX in this region that affects E346 and S351 but is also consistent with these residues having at least partial exposure to the pore. In support of this concept, A345, E346, and L350 all cluster with side chains

on the same face of the segment throughout the ensemble of structures. Although S351 is consistently (37/40 ensemble members) on the opposite face of the peptide, this observation may be explained by the rotation mechanism suggested by Landau *et al.* (14).

Positively charged MTSET but not negatively charged MTSES inhibited NHE1 activity in the E346C and S351C mutants. This contrasts with the results for the F161C mutant of TM IV that was inhibited by both compounds (27) but mirrors results with TM VII (45). MTSET may disrupt cation translocation by direct electrostatic repulsion, whereas negative MTSES would not. Alternatively, MTSES may not be able to react with these amino acids because of repulsion on the protein surface from negatively charged amino acids important in ion coordination (46). Local protein conformation and chemistry have been shown to affect accessibility to sulfhydrylreactive reagents in both K⁺ channels (47) and in the FMRF-amide-activated sodium channel (48). The E346C cNHE1 mutant exhibited a higher degree of kinetic inhibition for the same measured parameters as S351C (1) and was similarly affected by MTSET (inhibition) and MTSES (no inhibition). In both topology models (13, 14) S351 is located in the intramembrane region of the protein. Therefore, our results are consistent with S351 being pore-lining in both cases and MTSET obstructing the pore. In the first topology model (13), E346 is also in the intramembrane region and should be pore-lining, potentially on the same face of a TM segment as S351. However, our structural analysis did not place these residues on the same face, and only 3/40 ensemble members show this positioning. This may suggest an extracellular loop position for E346, as proposed by Landau et al. (14). MTSET modification could then obstruct cation transport by preventing entry to the pore (E346).

The observed increase in $K_{m(Na^+)}$ for S351C mutants (in kinetic studies by our collaborators detailed in the published manuscript) is consistent with at least moderately reduced extracellular coordination efficacy, and may therefore be supportive of

a role in the extracellular cation funnel for S351 as suggested by Landau *et al.* (14). The decrease in $V_{max(Na^+)}$ may imply a measurable contribution to inhibition by a perturbation in overall pore structure or that ion coordination by S351 is rate-limiting (*i.e.*, that we are not simply observing reduced electrostatic interaction that can be overcome by ligand saturation). Finally, the reduced V_{max} values for H⁺ transport and especially the reduced intracellular (*i.e.*, allosteric) activation of S351C cNHE1 by H⁺ are in agreement with an overall perturbation in tertiary structure.

Based on dihedral restraints and rmsd analysis, our data suggest that M340-S344 is helical, and although this is consistent with these residues lining a TM segment as they do in both models, the lack of contiguous α -helical character observed in the ensemble C-terminal to this segment until the second major helical segment (I353-S359) would be consistent with the extracellular loop assignment of residues 345-352 (14). The observed pivot at S351 (Figure 2.7 on page 22) also supports the possibility of an adjacent flexible extracellular loop at the location suggested by Landau *et al.* (14). E346 and G352 have been implicated as being critical in NHE1 inhibitor binding (17, 18). Placement of these residues at or near the extracellular surface is consistent with a site of drug interaction.

A distorted and interrupted helix with a bent L-shape would result if the peptide NMR structure was treated as a single TM segment (13). The bent structure we observe is consistent with a eukaryotic membrane span, the distance between C^{α} of S338 and S359 is 28 ± 2 Å in our structures. Conversely, if the Landau *et al.* (14) topology is correct, residues H349 and V362 would be at the extracellular and intracellular faces, giving a transbilayer length of 19 ± 1 Å, a length typically assumed to be insufficient to span a eukaryotic membrane (43). To attempt to resolve these topological issues, our collaborators performed a series of experiments with amino acids 345-348 to determine the accessibility to the extracellular surface. However, it was not possible to get consistent results that either verified or disproved their

extracellular or TM location (not shown). Even when externally accessible residues are detected, they are sometimes assigned intracellular locations using the argument that they represent pore-lining residues (13), making assignment of location somewhat arbitrary. The functional studies (by our collaborators) showing inhibition by MTSET or our structural studies on the isolated TM IX peptide provided valuable data on the importance of these residues in function, but they are unable to shed light on their precise topology.

We found that amino acid M363 displayed an elevated dispersion of backbone dihedral angles, and this may suggest functionally important flexibility at this position (Figure 2.8 on page 23). However, the functional work of our collaborators showed that the M363C mutation did not eliminate activity and that it did not react with MTSET or MTSES (1), which is somewhat contradictory to the idea that it is critical to function. Wakabayashi et al. (13) suggested that M363C is in an extracellular loop. Landau et al. (14) placed M363 in an intracellular loop. Our results strongly support M363 as a loop residue displaying a high degree of flexibility, but they cannot localize this residue to either face of the membrane nor assign a critical pore-lining role to this amino acid.

Overall, the combination of my NMR structural studies with the work of our collaborators provides a detailed structural and functional picture of the functionally critical amino acids 339-363 of the NHE1 isoform of the Na⁺/H⁺ exchanger. Our collaborators demonstrate that 5 of 25 residues are very sensitive to mutation to cysteine, and that E346 and S351 are involved in cation translocation and likely line the cation pore (1). The ensemble of structures, representing a kinked helical peptide, is similar to that previously reported for TM VII (22), but with a larger bend angle at the pivot point, S351. Amino acids M340-S344 and I353-S359 are helical. To resolve whether amino acids 339-363 represent one TM segment or parts of two, a full-length structure of NHE1 is necessary. It is encouraging that expression and purification

of full-length NHE1 has been achieved, but currently only a low-resolution structure obtained by electron microscopy is available (41).

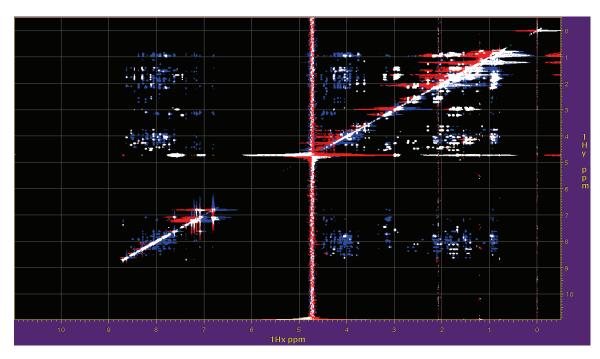

Figure 2.1: The NHE1 TM IX construct in DPC micelles was studied by TOCSY (white peaks) and NOESY (blue peaks) NMR experiments. There are substantially more peaks in the ¹H-¹H NOESY (225-ms mix) experiment than in the ¹H-¹H TOCSY (60-ms mix; decoupling in the presence of scalar interactions spin lock) on an 800 MHz spectrometer. This is consistent with the detection of through-space interactions in the NOESY and the restriction to scalar correlations in the TOCSY.

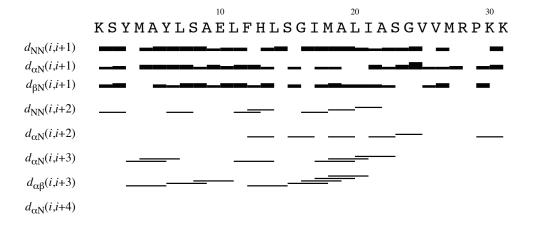

Figure 2.2: A representation of NOE contacts, which are limited to internuclear distances of ≤ 6 Å, between residues in the context of the primary sequence of NHE1 TM IX. This representation is modified from CYANA (L.A. Systems, Inc.) output and is consistent with the contacts outlined in Figure 2.3 on page 18 (*i.e.*, consider the paucity of long-range NOE restraints).

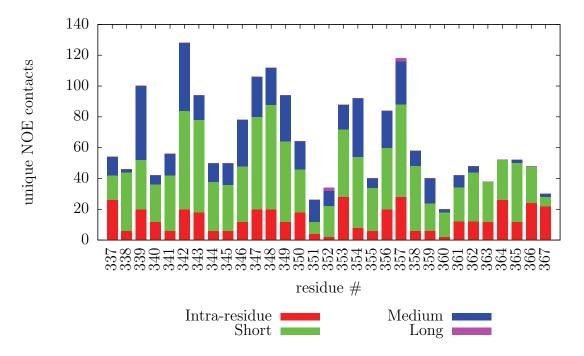

Figure 2.3: The number of per-residue unique NOE contacts in the final set of NMR restraints for NHE1 TM IX is summarized in this stacked histogram modified from CYANA (L.A. Systems, Inc.) output. Medium range restraints vary between 2 and 4 positions in the primary sequence, while long range restraints are five or more residues apart.

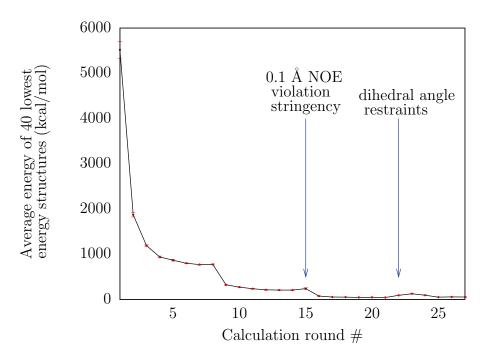

Figure 2.4: Tracking the total energy from each of the 27 rounds of XPLOR-NIH structure calculations for NHE1 TM IX. After each round, the average energy and standard deviation of the 40 lowest energy structures (out of 100 produced) were calculated. Iterative refinement of NOE restraints progressed by allowing restraints with violations > 0.5 Å in > 50% of structures to be lengthened, and after round 15 restraints with violations > 0.1 Å in > 25% of structures were lengthened. The latter progression in NOE restraint stringency clearly resulted in a reduction in average total energy for the calculated ensemble. After round 21, dihedral angle restraints consistent with α -helicity were imposed over candidate helical residues based on secondary chemical shifts. The new restraints account for the rise in total energy in round 22, and energy returns to the optimized level after subsequent rounds.

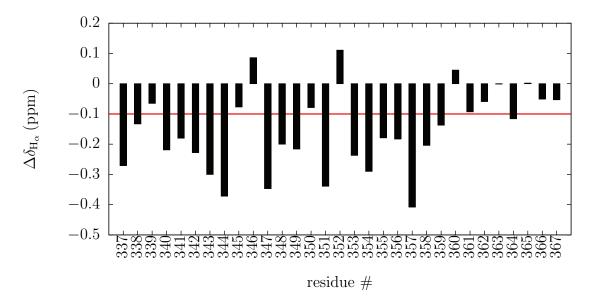

Figure 2.5: The secondary chemical shift $(\Delta\delta)$ for NHE1 TM IX H_{α} nuclei is calculated as $\delta_{H_{\alpha}} - \delta_{\rm random\ coil}$. The random coil values for each of the amino acids were obtained from (49), and observed shifts upfield to random coil values are consistent with helicity. Specifically, the widely-used chemical shift index (CSI) uses a secondary chemical shift requirement of < -0.1 as an indicator of α -helical secondary structure (50), and the red horizontal line marks this threshold.

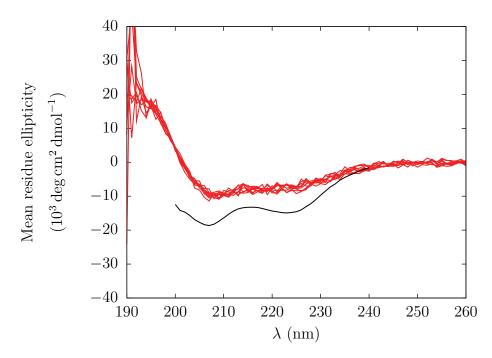

Figure 2.6: The synthetic NHE1 TM IX peptide NMR sample was diluted to produce a solution composed of ~10 μ M peptide and ~3 mM deuterated DPC (pH ~4.8). Nine replicate CD measurements were collected over three separate days on a Jasco J-810 spectropolarimeter at 30 °C in a 0.1 cm path length water-jacketed cell, and these results are plotted in red. For comparison, the predicted CD spectrum for a peptide with ~39 % α -helical content is shown in black (prediction by the K2D algorithm (23)).

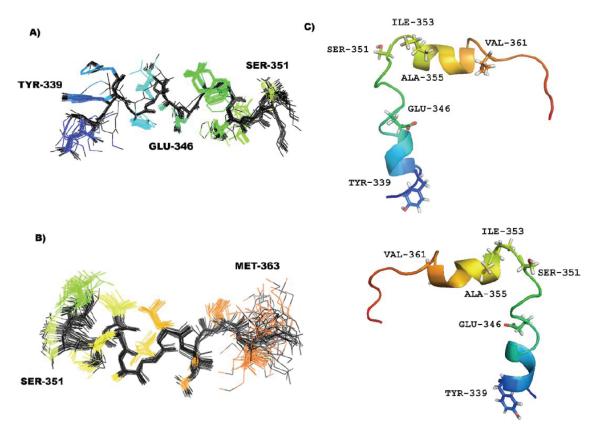

Figure 2.7: Assessment of superposable segments of the NHE1 TM IX NMR ensemble was performed using the LSQKAB program of the CCP4 suite (32), with evaluation of optimal superposition using criteria that include minimization of both local and global rmsd. The results include two superposable segments: between residues 337-350 (A) and 352-362 (B). Both of these segments have been extended in this figure to include the putative pivot point at S351, which was also found to be critical for NHE1 activity. Other functionally relevant residues (Y339, E346) and the strikingly mobile M363 (see Figure 2.8 on page 23) are also highlighted. Two alternative views of the lowest energy NHE1 TM IX NMR ensemble member are also shown (C) with colouring from N-terminus (blue) to C-terminus (red). This is a representative structure, but the angle of the kink near S351 and side chain positions are variable in the ensemble.

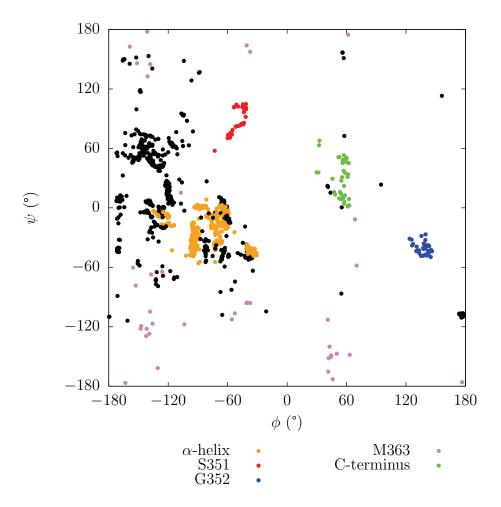

Figure 2.8: Ramachandran plot for the residues of NHE1 TM IX with ϕ and ψ values from all 40 retained structures in the final NMR ensemble. α -helical residues, the penultimate C-terminal residue, the pivot point at S351, the well-clustered G352 dihedral angles, and the strikingly variable M363 dihedral angles are all highlighted.

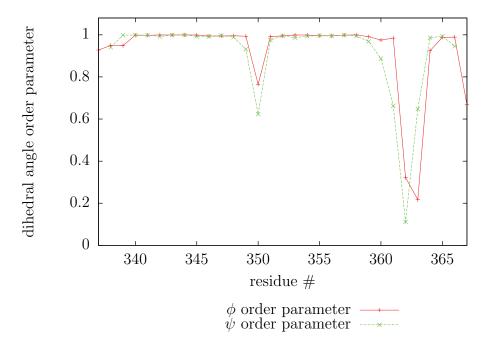

Figure 2.9: The backbone dihedral angle order parameters (ϕ, ψ) were calculated for each residue in the NHE1 TM IX construct based on the final ensemble of retained structures, as described in (51). An order parameter of 1.0 indicates a dihedral angle that is consistent over the entire ensemble of NMR structures, a value of 0.0 is consistent with a completely random distribution of dihedral angles, and intermediate values represent varied degrees of dihedral angle fluctation within the NMR ensemble. Angular standard deviation is not used because truly random angle distributions are not defined.

Table 2.1: Summary of statistics for the final retained ensemble of 40 NMR structures (out of 100 calculated) for NHE1 TM IX.

Chapter 3

NMR Spin Relaxation Studies And The Dynamics Of NHE1 TM VII (Based On The Published Manuscripts (2) And (3))

3.1 Introduction

The previous chapter (chapter 2 on page 3) introduced the biological significance of the human NHE1 protein and I presented my structural NMR studies of the ninth TM segment of NHE1. The structures of a number of other NHE1 TM segments have also been studied by NMR spectroscopy in membrane-mimetic environments as part of a "divide and conquer" approach to the study of NHE1 structure. A common theme in many of these structures is the presence of a disruption in helicitiy—a kink in the regular secondary structure which may confer structural flexibility. However, apparent flexibility in an NMR ensemble may result from a lack of observable NOE restraints and not necessarily true motion in the peptide. NMR spin relaxation experiments are well suited to probing the ps-ns and μ s-ms time scale dynamics of amino acids, and I employed ¹⁵N backbone relaxation NMR experiments to probe the dynamics at selectively labelled positions in the NHE1 TM VII peptide construct reconstituted in DPC micelles. This introduction is based on a review of NMR spin

relaxation I published (3), and followed by a section based on the NHE1 TM VII spin relaxation studies I published (2).

3.1.1 Introduction To NMR Spin Relaxation

NMR spectroscopy is a powerful technique for studying the dynamics of biomolecules using spin relaxation experiments. Frequently, when studying a protein or peptide, the objective of a backbone ¹⁵N NMR dynamics study is to identify and differentiate restricted versus mobile residues in the primary sequence and relate this information to structure and function. This type of information has lead to many biologically relevant insights, with some recent examples following. ¹⁵N relaxation analysis of PSE-4 β -lactamase revealed μ s-ms time scale mobility for residues in the active site, consistent with the ability of this enzyme to degrade a number of diverse β -lactam antibiotics (54). General odorant-binding proteins (GOBPs) also have promiscuous interaction profiles, and a recent relaxation study of honeybee GOBP ASP2 revealed increased backbone ¹⁵N-¹H ms time scale mobility at the ligand entry site (55). ¹⁵N spin-lattice (T_1) , spin-spin (T_2) , and heteronuclear nuclear Overhauser effect (NOE) relaxation measurements revealed positions of active site flexibility in the essential dihydrofolate reductase enzyme from Bacillus anthracis (56), the highly resilient causative agent of anthrax. This structure-activity relationship is important for the design of potent inhibitors.

Binding events are also frequently detected by NMR relaxation. The acidic residues in calcium-binding domain 1 of the Na⁺/Ca²⁺ exchanger are significantly restricted upon binding of calcium (57). In contrast, *Escherichia coli* 6-hydroxymethyl-7,8-dihydropterin pyrophosphokinase exhibits increased ¹⁵N-¹H mobility when binding substrate analogues, mobilizing loops that may stabilize the transition state (58). Based on a September 2009 ISI Web of Knowledge (Thomson Reuters Inc.) search, nearly 2000 original research articles and 170 reviews cite the original Lipari and Szabo (6) model-free approach to NMR relaxation analysis. This demon-

strates not only the popularity of the Lipari-Szabo model-free approach but, more generally, the widespread degree to which biomolecular NMR relaxation methods are used. Accordingly, the field of NMR spin relaxation has been extensively reviewed (59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75).

Understandably, in the more than 60 years since the first detection of an NMR signal (76, 77), the methodologies and computer software employed for extracting dynamics information have diverged. In practice, several programs may be compared in the calculation of relaxation parameters. d'Auvergne and Gooley (78) present a detailed analysis of the limitations of various algorithms used for the interpretation of NMR relaxation data. For the NMR spectroscopist uninitiated to spin relaxation theory, however, the ready analysis of experimental data is compounded by the diversity of analytical approaches, the use of CGS versus SI units in defining constants and equations by different authors, and the lack of available sample calculations. It is therefore difficult to assess the quality of newly collected relaxation data without prior experience in the field. I will therefore review relaxation parameters and describe a web interface for graphing the theoretical trends of relaxation parameters to provide a first-check as to whether collected relaxation data matches with the predictions of theory. This is a crucial concern for the NMR spectroscopist preparing to embark on an exhaustive relaxation analysis for the first time. Thorough theoretical reviews of NMR spin relaxation analysis are available (i.e., (71, 69)), but are not necessarily accessible to the spectroscopist new to relaxation. Although our focus is on solution-state peptide and protein ¹⁵N-backbone NMR relaxation experiments, the fundamental principles are applicable to other biomolecular systems, and a diverse set of examples are considered that may be placed in an experimental context using the new web interface I introduce.

Before diving into the specifics, it is important to understand the microscopic origins of spin relaxation in solution-state NMR. Perhaps the most intuitive way to

understand the NMR spin relaxation process is to first consider the fully relaxed thermal equilibrium state (79). At thermal equilibrium, two important conditions are met: 1) the populations of each spin state (i.e., α and β , for a spin 1/2 nucleus) are given by the Boltzmann distribution; and 2) all coherence between α and β spin-states is lost. Spin excitation with an on-resonance radiofrequency pulse may disturb the equilibrium and break either of these conditions. For example, a π -pulse inverts the spin state populations (i.e., α and β populations are exchanged, for a spin 1/2 nucleus), breaking the condition of a Boltzmann distribution. Alternatively, a π /2-pulse produces coherent transverse magnetization, breaking the second equilibrium condition. Return to thermal equilibrium occurs by two relaxation mechanisms.

The restoration of the Boltzmann distribution, or spin-lattice relaxation (characterized by a time constant T_1), occurs as a result of the coupling of excited spins with the surrounding environment, termed the lattice for historical reasons (80). Random reorientation of molecules in a liquid modulates the local magnetic field experienced by a given spin. In typical macromolecular cases, two orientationally dependent components come into play: the magnetic fields induced by direct dipole-dipole coupling with neighbouring spins, which depend upon relative dipole orientation; and the fields caused by molecular electron currents, which depend upon molecular orientation relative to the static magnetic field. These fluctuations drive spin-lattice relaxation by inducing transitions between spin states, specifically by field fluctuations at the Larmor frequency of the nucleus.

Spin-spin relaxation (characterized by T_2) refers to the restoration of the second condition of thermal equilibrium, a loss of coherence between spins, as a result of individual variation in Larmor frequency for each spin due to local field fluctuations (81). Unlike spin-lattice relaxation, spin-spin relaxation of a given nuclear spin does not rely on a transition of *total* spin state; however, field fluctuations are dependent on spin state transitions by neighbouring nuclei.

Enhancement of magnetization relative to the thermal equilibrium level by the heteronuclear NOE is also frequently exploited for dynamics measurements in biomolecular NMR. The NOE is, of course, dependent upon the dipole-dipole distance and the relative gyromagnetic ratios of each spin (79). Assuming that these factors are known for a given pair of heteronuclei in sufficient proximity for the NOE to occur, the enhancement of longitudinal magnetization for a non-irradiated spin that is dipole-dipole coupled to a spin being irradiated by a weak radiofrequency field depends on cross-relaxation between the irradiated spin and and non-irradiated spin. The cross-relaxation rates (zero-quantum and double-quantum transitions) depend on the molecular tumbling rate (81).

It is intuitive that spin relaxation is sensitive to dynamics, the motion of bond vectors for example, because each of these relaxation processes is driven by motion. After collection of T_1 , T_2 , and NOE relaxation data, there are two main routes for mathematical analysis: 1) the Lipari and Szabo (6) model-free approach mentioned above; and 2) reduced spectral density mapping (8, 9).

The model-free approach provides intuitive motional parameters. S^2 , the order parameter, is a measure of motion amplitude and ranges from 0 for an isotropic bond vector to 1 for complete restriction of motion. S^2 does not provide sufficient information to obtain the path or model of motion for a bond vector—hence the model-free label for this technique (59). The model-free approach assumes separability of internal bond vector motion and overall molecular motion. The former timescale is quantified as the effective internal correlation time, τ_e , whereas the latter is referred to as the overall rotational correlation time, τ_c . These three model-free parameters are generally easier to interpret than the spectral density values obtained by reduced spectral density mapping.

The spectral density function, $J(\omega)$, is the Fourier transform of the rotational correlation function. In ¹⁵N biomolecular spin relaxation, the correlation function is

typically defined for the motion of a 15 N- 1 H bond vector (6). $J(\omega)$ is thus defined as the probability of observing rotational motion at a particular frequency, ω . The case of J(0), for example, could represent the (relative) population of a particular backbone 15 N- 1 H bond vector that has zero frequency, or that is rotationally immmobile, at any given time. As a whole, spectral density mapping provides the capability to demonstrate the relative degree of high- to low-frequency oscillations for a given bond vector (extensively reviwed in (64)). It has one significant advantage over the model-free approach, in that it does not require that internal bond vector motions occur independent of overall molecular tumbling.

Motional separability tends to be a particularly poor assumption for non-globular, unfolded proteins (59). As an example, Eliezer et al. (82) characterized the progression of myoglobin from an unfolded precursor to the fully folded globular protein by NMR relaxation experiments, demonstrating much greater mobility for residues in the unfolded versus folded state of the protein. Clearly, local reptation implied by dramatically increased mobility on a per-residue basis in an unfolded protein makes the separability of internal and overall motions unlikely. In any situation where this separability is suspect, spectral density mapping as opposed to, or at least in parallel to, model-free analysis may be essential (59).

Although I focus here on 15 N as a probe of local dynamics, 2 H and 13 C isotopes may also be used to study the dynamics of biomolecules, as is especially popular for the study of amino acid side chain motion. Isotope enrichment is typically employed, but it should be noted that 13 C relaxation experiments may also be performed at natural abundance (83). Uniform labelling with 13 C and fractional labelling with 2 H was used with 2 H-NMR relaxation experiments to study the side chain methyl group dynamics in the C-terminal SH2 domain of phospholipase- $C_{\gamma 1}$ (84), the first solution-state NMR study of this kind. The relaxation of a deuteron is dominated by the quadrupolar interaction that can simplify interpretation of relaxation data relative

to other nuclei, which can have multiple significant contributions to relaxation. Tugarinov et al. (85) introduced a new set of deuterium NMR relaxation experiments, allowing the study of side chain dynamics for large (~100 kDa) proteins using malate synthase G (a 723 residue single polypeptide chain enzyme) as the test system for the experiments. Experiments using different methyl isotopomer probes (CHD₂; CH₂D) were consistent with each other, with previous experiments, and with molecular dynamics simulations. A comparison of the strengths and weaknesses of ²H and ¹³C spin relaxation experiments has been conducted on recombinant human ubiquitin (86). ²H relaxation methods were better for providing methyl symmetry axis information with limited data, whereas ¹³C relaxation provided more robust model-free parameters for the time scale of methyl rotation and methyl symmetry axis motion.

3.1.1.1 Assessing The Trend Of T_1 , T_2 , And NOE With Magnetic Field Strength

Any biological insights from NMR relaxation result from translating raw experimental peak height or volume data into a set of intuitive relaxation parameters relating a residue to its mobility. The NMR pulse sequences and the calculation of initial 15 N T_1 , T_2 , and NOE values are well described by the seminal work of Farrow et al. (87). Since it is quite common to perform these experiments at multiple magnetic field strengths (8, 88), one of the first checkpoints of data integrity is the trend of T_1 , T_2 , and NOE with magnetic field strength. For this reason, I have created an online plotting tool (available at http://structbio.biochem.dal.ca/jrainey/Tyler_relaxation/) using the Python code in appendix C on page 253, which accepts a number of NMR relaxation parameters that can be tailored to a specific system to produce the theoretical trends of the relaxation times T_1 and T_2 (as well as the related rates R_1 and R_2) and the heteronuclear NOE with magnetic field strength. Initially, the user may not have an accurate estimate of certain relaxation parameters, τ_c , S^2 , τ_c , which are discussed in detail below. In these cases, the user may

input minimum and maximum values, which are plotted as a series of graded values. A set of detailed tables of parameter values for various peptide/protein systems are available in the published manuscript (3).

3.1.1.2 The Overall Rotational Correlation Time, τ_c

The overall rotational correlation time represents the time required for the molecule to tumble through one radian in an arbitrary direction (81). It depends on the size and shape of the molecule and the solvent viscosity. Some studies are consistent with the general rule of 0.5 ns overall correlation time per 1 kDa of molecular weight in a system (89, 90, 91). In contrast, there are also several cases where this estimate is not accurate (92, 93, 94). τ_c is normally observed to decrease with increasing temperature. Recombinant human ubiquitin τ_c varied as follows: 8.84 ns (5 °C), 6.36 ns (15 °C), 4.71 ns (25 °C), 3.58 ns (35 °C), 2.77 ns (45 °C), and 2.17 ns (55 °C) (95). A progressive drop in τ_c with increasing temperature was also observed for a calmodulin-peptide complex: 11.81 ns (22 °C), 8.26 ns (35 °C), 6.33 ns (47 °C), 5.00 ns (60 °C), and 4.10 ns (73 °C) (96).

In the case of proteins solvated by micelles or bicelles in solution, the "aggregate weight" versus molecular weight must be taken into account, making estimation of τ_c more difficult. For example, Yan et al. (94) proposed that a concentrated protein solution can increase the aggregation number of micellar systems, as discussed previously (97). Furthermore, 100 mmol/L NaCl can increase the SDS aggregation number from approximately 60 to 91 (98). Elevated aggregation numbers in these situations may account for increases in observed correlation times.

One simple theoretical approach for the estimation of τ_c is the Stokes-Einstein-Debye relation, which depends on isotropic motion for approximately spherical globular proteins (80). Of course, many proteins are not spherical and, even in the absence of micelles or bicelles, there is still the possibility that the protein itself aggregates in solution. More sophisticated approaches to estimation of τ_c include a relationship

between rotational correlation time and solvent accessible surface area (99), hydrodynamic calculations (100), and NMR relaxation interference experiments (101). Independent experimental measurement of τ_c may also be performed by time-resolved fluorescence spectroscopy or light scattering (80). However, most conveniently, NMR relaxation experiments are an excellent method for estimating τ_c if the protein size is less than 30 kDa (101). The normal procedure is to use a ratio of transverse $(R_2 = \frac{1}{T_2})$ and longitudinal $(R_1 = \frac{1}{T_1})$ relaxation rates (91, 102, 103, 104). Large deviations between theoretical predictions for τ_c and the experimentally determined value may suggest oligomerization.

3.1.1.3 The Generalized Order Parameter, S^2

The generalized order parameter (S^2) , introduced in the development of the model-free formalism by Lipari and Szabo (6, 7), is an intuitive way to characterize the amplitude of internal picosecond-nanosecond timescale motions of bond vectors studied by NMR relaxation experiments. S^2 values are always between 0 (fully isotropic) and 1 (a completely restricted bond vector). In the case of the extended Lipari-Szabo formalism (105), $S^2 = S_f^2 S_s^2$, where S_f^2 and S_s^2 are order parameters representing fast (ps timescale) and slow (ns timescale) internal motions, respectively. In both formalisms, the degree of motional restriction does not specify a particular model of motion, hence the "model-free" terminology.

Intuitively, S^2 is expected to decrease at higher temperature due to increased thermal motion, although only a 0.03 average decrease in S^2 was observed between 12 and 37 °C for Ribonuclease H (106). ¹⁵N-¹H NMR relaxation experiments on recombinant human ubiquitin at temperatures ranging from 5 to 55 °C also demonstrated a small drop in the order parameter as temperature was increased, with average $\frac{dS^2}{dT} = -2.3 \pm 0.95 \times 10^{-3} \text{ K}^{-1}$ (95). Similar studies on a calmodulin-peptide complex over the range of 22-73 °C also demonstrated a small $\frac{dS^2}{dT}$ of $-1.5 \times 10^{-3} \text{ K}^{-1}$, on average, with S^2 actually increasing slightly from the minimum value at 60 °C to

the value obtained at 73 °C (96). The loop residues not involved with Ca²⁺ binding had order parameters lower by almost 0.10, and had the greatest temperature dependence; notably residues 115 and 116 had $\frac{dS^2}{dT} \sim -5 \times 10^{-3}$ K⁻¹. Futhermore, ¹⁵N-H order parameters showed significantly larger changes with temperature for the unfolded states of staphylococcal nuclease (SNase) and the N-terminal SH3 domain of drk (drkN SH3) versus their respective folded states (107). For SNase, between 15 and 32 °C, $\Delta S_{avg}^2 = 0.045 \pm 0.031$, but $\Delta S_{avg}^2 = 0.143 \pm 0.032$ for the partially unfolded SNase mutant $\Delta 131\Delta$. The authors also observed this striking contrast between the folded drkN SH3 ($\Delta S_{avg}^2 = 0.004 \pm 0.036$) and the protein denatured in 2 mol/L GuHCl ($\Delta S_{avg}^2 = 0.087 \pm 0.025$) for a temperature change between 14 and 30 °C. These changes were related to the different contributions of motion to the overall heat capacity of folded and unfolded proteins. Clearly, the folding state of a protein is relevant to the temperature sensitivity of ¹⁵N-H order parameters.

An extensive database analysis of the relationship between generalized order parameter values and protein secondary structure has been conducted (108). Of the 1855 order parameters surveyed from 20 proteins, $S_{avg}^2 = 0.839 \pm 0.106$. The authors find that the backbone mobility of an amino acid is strongly correlated with its side chain size, and to a lesser extent, the size of the neighbouring residue side chains. The smallest residue, glycine, is also the most mobile $(S_{avg}^2 = 0.81 \pm 0.14)$, whereas tryptophan, which has the largest volume, is the most restricted $(S_{avg}^2 = 0.87 \pm 0.07)$. It is commonly reported that S^2 is larger in canonical secondary structure elements versus disordered loops (109), but (108) report only a slightly more mobile average for residues in loops $(S_{avg}^2 = 0.81 \pm 0.11)$ versus helices $(S_{avg}^2 = 0.88 \pm 0.07)$ or β -structures $(S_{avg}^2 = 0.85 \pm 0.07)$. Terminal residues were mobile $(S_{avg}^2 = 0.61 \pm 0.24)$, as might be expected for these often less-structured regions.

It must be noted that the 20 proteins in the database used in (108) are all stable and folded. Intrinsically disordered proteins (IDPs) are increasingly recognized as

biologically important effectors with a high binding plasticity (110, 111), which may exhibit a very different set of dynamic behaviours. Human securin, a regulator of cell division, is a 202 residue protein with 24 prolines, and is considered an IDP (112). NMR relaxation analysis is consistent with transient structuring in certain segments of securin. There is a central plateau for relaxation rates in the primary sequence and higher rates at the termini, although no model-free parameters were provided. Transient helical structuring was also observed in the IDP Sml1 based on chemical shifts, and NMR relaxation results $(R_1, R_2, \text{ and steady-state NOE})$ consistent with restricted motion for residue segments 4-20 and 60-86 (113). In another study, the Sml1 backbone structure was incredibly flexible with all $S^2 < 0.6$, except for the transiently helical regions (114). A remarkably similar degree of flexibility was observed for the backbone of the N-terminal half of hepatitis C virus core protein (C82), also an IDP, with $S_{avg}^2 = 0.59 \pm 0.04$ (115). Similarly, the natively unfolded propertide subtilisin (PPS) was flexible with $S_{avg}^2 = 0.57 \pm 0.06$ (116). To fit the PPS $^{15}{\rm N}$ relaxation data, the authors modified the traditional model-free approach by fitting each residue with a distribution of rotational correlation times to reflect the ensemble of states for the unfolded protein. S^2 and τ_e , the next parameter in our survey, were both separately fit for each individual residue. Clearly, different analytical strategies are being explored for the dynamics of natively unfolded proteins, and S^2 values are frequently lower on average than those considered canonical for structural proteins.

It has recently been suggested that the order parameters determined from modelfree analysis are merely starting values (117). A thorough assessment of N-H bond vector reorientational motion involves a variety of order parameter simulation methods that provide separate pieces of dynamic information: 1) the isotropic reorientational eigenmode dynamics method (iRED) for assessing separability of internal and overall motion as assumed by the Lipari-Szabo approach; 2) a first-order expansion in local variances and covariances accounts for contributions from local dihedral angle fluctuations to the order parameter; 3) the three-dimensional Gaussian axial fluctuation (GAF) method describes anisotropic peptide plane motion (118); and 4) the local contact model provides direct estimation of order parameter from 3D structure. Surprisingly, the local contact model produces an excellent agreement between observed S^2 values and values predicted directly from X-ray crystallography or NMR structures of lysozyme, ubiquitin, interleukin-4, calmodulin, and an HIV-1 proteaseligand complex, suggesting a strong link between structure and dynamic information (119).

3.1.1.4 The Effective Internal Correlation Time, τ_e

The effective internal correlation time (τ_e) measures the time scale for internal motions of bond vectors sweeping through an amplitude quantified by the order parameter. τ_e is notoriously difficult to interpret quantitatively because it is a complex combination of geometric factors (6, 7, 120). Low τ_e precision from model-free analysis is especially pronounced for restricted residues $(S^2 \geq 0.8)$ (121), as I have recently observed for a ¹⁵N NMR relaxation analysis of the seventh TM segment of the Na⁺/H⁺ exchanger isoform 1 (2). Palmer (68) specifically indicates that τ_e is imprecisely determined and usually not analyzed in detail. In the case of the extended Lipari-Szabo formalism, the parameter is expanded into τ_f and τ_s , which are internal correlation times for bond vector motions on picosecond and nanosecond timescales, respectively (105). The authors report ranges of 200-300 ps for τ_f and 1-3 ns for τ_s for relaxation studies on staphylococcal nuclease and interleukin-1 β . The extended method is normally used when timescales for internal motions differ by at least one order of magnitude. Typically, τ_e is on the picosecond timescale and overall tumbling occurs on the nanosecond timescale.

3.2 NMR Spin Relaxation Studies Of NHE1 TM VII

The above description of NMR spin relaxation, based on my published manuscript (3), provides the necessary foundation to understand the model-free and reduced spectral density mapping analyses of NHE1 TM VII in DPC micelles. The TM VII work is based on another published manuscript (2) and it is detailed below.

3.2.1 NHE1 TM VII Background

I have used ¹⁵N NMR relaxation methods to study the dynamics of a ¹⁵N-labelled peptide of TM VII of NHE1 and I correlate these studies with structural information. Previous studies on functional aspects of the full-length NHE1 protein were performed using alanine scanning and insertion mutagenesis at the TM VII segment (residues 251-273) (22). Ala is the fourth most common amino acid in protein TM segments and is the fifth most effective helix-inducer in a hydrophobic environment (122, 123). Ala substitutions at 13 of 22 TM VII residues resulted in severely reduced activity in the full-length NHE1 protein (22). Beyond perturbing intramolecular interactions or removing key chemical moieties required for ion transport, if flexibility at TM VII is important for NHE1 function (i.e., ion transport) Ala substitutions may interfere by promoting the structural rigidity of an α -helix in addition to replacing important charged or steric residues. The potential importance of flexibility in TM VII is spurred by the ensemble of NMR structures for the peptide in DPC micelles, which show an α -helix interrupted at G261-S263 (22). E262 is critical to activity in the full-length NHE1 protein and, more specifically, an acidic residue at this position is hypothesized to be important for cation coordination (124). Since E262D retains much of the NHE1 activity (124), it is possible that the reduced helix forming propensity of acidic residues in comparison to Ala in addition to charge retention is important for conserving both a disruption in helicity and ion coordination (22). The

G261A and E262A mutants of NHE1 were 50 % and 48 % less active than the wildtype protein, respectively, even after correction for reduced expression and targeting (22). The G261-S263 region in the TM VII peptide in DPC micelles was found in two predominant conformations, one in which G261-S263 is fairly extended and the N- and C-terminal helical regions are distal to each other and the other in which the helical regions are in close proximity and G261-S263 is allowing the formation of a tight kink. Observation of a single set of NMR chemical shifts in this region implies relatively rapid interconversion between conformations, and hence a rather dynamic structure for the TM segment despite its reconstitution in DPC micelles. Given the reduction in NHE1 activity following Ala substitution mutagenesis at G261 and E262 that were observed previously (22), a new set of mutations were also explored by our collaborators (lab of Dr. Fliegel, University of Alberta) with the goal of testing the effect of further restriction of motion in the TM VII segment. For this purpose, mutation to Ile was chosen since Ile is the most common amino acid found in protein TM segments and, of the 20 common amino acids, has the highest propensity for α -helix formation in a hydrophobic environment (122, 123). Herein, my NMR spin relaxation studies are presented in detail, while the details of collaborative mutagenesis studies are presented in the published manuscript (2).

3.2.2 Materials And Methods

3.2.2.1 Materials

Deuterium oxide (99.9% D), deuterium oxide (99.9% D) with 1% sodium 2,2-dimethyl-2-silapentane-5-sulphonate, and DPC-d₃₈ (99.1% D) were purchased from CDN Isotopes (Pointe-Claire, QC, Canada). A 535-PP NMR tube (Wilmad Glass Co., Buena, NJ, USA) was used for all NMR relaxation experiments.

3.2.2.2 Peptide Synthesis And Purification

The TM VII peptide (HINELLHILVFGESLLNDAVTVVLYKK; free N-terminus,

amide-capped C-terminus; the bold red-coloured residues having backbone ¹⁵N labels) was synthesized using solid-phase Boc chemistry (125) and purified as previously described (22). Peptide identity was confirmed by matrix-assisted laser desorption ionization mass spectrometry and by amino acid analysis (Institute for Biomolecular Design, Edmonton, AB, Canada).

3.2.2.3 NMR Spectroscopy

The NMR sample was prepared by dissolving \sim 770 μ M TM VII peptide in 90% $\rm H_2O$, 10% $\rm D_2O$ solution containing \sim 75 mM DPC-d₃₈. Chemical shifts were referenced to 2,2-dimethyl-2-silapentane-5-sulfonic acid at 1.0 mM. Solution pH was adjusted to 4.8 (deuterium isotope effects not taken into account), and all experiments were carried out at 30 °C for consistency with structural studies (22). One-dimensional 1 H observed, 15 N NMR relaxation experiments were performed on 500, 600, and 800 MHz (800 equipped with cyrogenic probe) Varian Inc. (Palo Alto, CA, USA) INOVA spectrometers, with parameters listed in Table 3.1 on page 55. The BioPack (Varian Inc.) gNhsqc pulse sequence (126) was used for measurement of 15 N relaxation of labelled TM VII residues. The 15 N relaxation rates were measured from 1D { 1 H- 15 N}-HSQC spectra. All spectra were processed and analyzed with VnmrJ 2.1B (Varian Inc.).

3.2.2.4 ¹⁵N Relaxation Parameters

¹⁵N relaxation time constants (T_1, T_2) and their standard errors from the covariance matrix were calculated using a nonlinear least-squares fit to a two parameter monoexponential decay using xcrvfit version 4.0.12¹. Errors for the first order rate constants (R_1, R_2) were propagated (127) from the time constant errors using:

$$\delta R_i = \frac{|R_i|}{|T_i|} \delta T_i \tag{3.1}$$

¹http://www.bionmr.ualberta.ca/bds/software/xcrvfit/

where R_i and T_i represent a pair of rate and time constants, respectively.

Steady-state $\{^{1}H\}^{-15}N$ NOE values were calculated using the software relax version 1.3.2 (78, 128) as the peak height (I) ratios in proton saturated versus reference spectra:

$$NOE = \frac{I_{\text{sat}}}{I_{\text{ref}}} \tag{3.2}$$

Standard deviation (σ) was propagated from the root-mean-square baseline noise as previously reported (87):

$$\sigma_{\text{NOE}} = \text{NOE} \quad \sqrt{\left(\frac{\sigma_{I_{\text{sat}}}}{I_{\text{sat}}}\right)^2 + \left(\frac{\sigma_{I_{\text{ref}}}}{I_{\text{ref}}}\right)^2}$$
 (3.3)

3.2.2.5 Model-Free Calculations

The calculated T_1 , T_2 , and NOE values at three field strengths were used to determine the model-free parameters τ_M (overall rotational correlation time), S^2 (generalized order parameter), and τ_e (effective internal correlation time) through spectral density function fitting using the following relaxation expressions (129, 8):

$$\frac{1}{T_1} = \left(\frac{d^2}{4}\right) \left[J(\omega_H - \omega_N) + 3J(\omega_N) + 6J(\omega_H + \omega_N) \right] + c^2 J(\omega_N)$$
 (3.4)

$$\frac{1}{T_2} = \left(\frac{d^2}{8}\right) \left[4J(0) + J(\omega_H - \omega_N) + 3J(\omega_N) + 6J(\omega_H) + 6J(\omega_H + \omega_N)\right] + \left(\frac{c^2}{6}\right) \left[3J(\omega_N) + 4J(0)\right]$$
(3.5)

NOE = 1 +
$$\left(\frac{d^2}{4}\right) \left(\frac{\gamma_H}{\gamma_N}\right) [6J(\omega_H + \omega_N) - J(\omega_H - \omega_N)]T_1$$
 (3.6)

where $d = \left[\frac{\mu_0 h \gamma_N \gamma_H}{(8\pi^2)} \left\langle \frac{1}{r_{\rm NH}^3} \right\rangle \right]$, $c = \left(\frac{\omega_N}{\sqrt{3}}\right) (\sigma_{\parallel} - \sigma_{\perp})$, μ_0 is the permeability of free space, ω_N and ω_H are the respective nuclear Larmor frequencies of ¹⁵N and ¹H, γ_N and γ_H are the respective gyromagnetic ratios of ¹⁵N and ¹H, h is Planck's constant, $r_{\rm NH}$ is the length of the amide bond, and σ_{\parallel} and σ_{\perp} are the parallel and perpendicular

components of the axially symmetric chemical shift tensor. A value of -160 ppm was used for $(\sigma_{\parallel} - \sigma_{\perp})$ (87, 130). The form of the spectral density function used in the Lipari-Szabo formalism is given by (6, 7):

$$J(\omega) = \frac{2}{5} \left\{ \frac{S^2 \tau_M}{[1 + (\omega^2 \tau_M^2)]} + \frac{(1 + S^2)\tau}{[1 + (\omega\tau)^2]} \right\}$$
(3.7)

where $\frac{1}{\tau} = \frac{1}{\tau_M} + \frac{1}{\tau_e}$.

Fitting of the model-free parameters τ_M , S^2 , and τ_e to the relaxation data was performed using a suite of Mathematica (Wolfram Research Inc., Champaign, IL, USA) notebooks previously described (131) but modified by Spyracopoulos to include data collected at multiple field strengths in a single calculation. Briefly, five forms of the spectral density function are considered to account for mixtures of motion on various time scales (131, 132). An optimization procedure is performed to fit the experimental input $(T_1, T_2, \text{ steady-state NOE})$ to each of these five mathematical models, labelled 1-5. The appropriate model for each of the residues is selected using the statistical approach of Akaike's information criteria (AIC) (133), and 100 Monte Carlo simulations were performed to estimate parameter errors (121).

3.2.2.6 Reduced Spectral Density Mapping

Using the reduced spectral density mapping approach (8, 9), measurement at three field strengths for the steady-state NOE, spin-lattice (T_1) and spin-spin (T_2) relaxation times of ¹⁵N allows for sampling of seven spectral density values describing the motion of the system (88). The spectral density values, under the high frequency approximation that $J(0.921\omega_H)$ and $J(0.955\omega_H)$ are both equivalent to $J(0.870\omega_H)$

(8), are obtained from the following set of equations:

$$NOE = 1 + \left(\frac{d^2}{4}\right) \left(\frac{\gamma_H}{\gamma_N}\right) \left[5J(0.870\omega_H)\right] T_1$$
(3.8)

$$R_1 = \left(\frac{d^2}{4}\right) \left[3J(\omega_N) + 7J(0.870\omega_H)\right] + c^2 J(\omega_N)$$
(3.9)

$$R_2 = \left(\frac{d^2}{8}\right) \left[4J(0) + 3J(\omega_N) + 13J(0.870\omega_H)\right] + \left(\frac{c^2}{6}\right) \left[3J(\omega_N) + 4J(0)\right]$$
(3.10)

Equations 3.8 to 3.10 allow solving for the three unknown spectral density functions $J(0.870\omega_H)$, $J(\omega_N)$, and J(0). The field-dependent $J(0.870\omega_H)$ and $J(\omega_N)$ alongside the field-independent J(0) give seven spectral density values for a given bond vector at three field strengths. Uncertainties in the values of spectral density functions were calculated by propagating the uncertainties of the independent variables using a sum of squares equation:

$$\delta q = \sqrt{\left(\frac{\delta q}{\delta x}\delta x\right)^2 + \dots + \left(\frac{\delta q}{\delta z}\delta z\right)^2}$$
 (3.11)

where x ... z represent any number of independent variables and δ values are parameter uncertainties (127).

3.2.2.7 Theoretical Calculations

The software Maple 11.02 (Waterloo Maple, Inc., Waterloo, ON, Canada) was used to predict the trend for T_1 , T_2 or NOE as a function of magnetic field strength according to equations 3.4-3.7 (prior to the development of the web-accessible program described in section 3.1.1.1 on page 33). Specifically, each of the three model-free parameters used to describe the motion of ¹⁵N-H bond vector (S^2, τ_e, τ_M) was independently varied to study the robustness of the trend of T_1 , T_2 or NOE with increasing magnetic field strength. τ_M of the NHE1 TM VII peptide in DPC micelles was esti-

mated using a T_1/T_2 fit strategy in the Mathematica notebooks introduced above, as previously described (87, 131).

3.2.3 Results

3.2.3.1 Relaxation Parameters: T_1 , T_2 , and NOE

A set of ¹⁵N NMR relaxation data ($T_1 = \frac{1}{R_1}$, $T_2 = \frac{1}{R_2}$, and NOE) was acquired at 500, 600, and 800 MHz for a specifically ¹⁵N labelled TM VII peptide in DPC micelles at 30 °C (*i.e.*, Figure 3.1 on page 52). The T_1 values are similar for all six ¹⁵N-labelled TM VII residues, with slightly lower values for L254 at 500 MHz and 600 MHz but not at 800 MHz (Figure 3.2 on page 53). There is a trend toward increasing T_1 at higher field strength, although the increase is within the bounds of experimental error. In contrast, T_2 values clearly decrease at higher magnetic field strength. For each magnetic field strength, the T_2 values are approximately constant over the six residues. The steady-state NOE values are also approximately constant over the six ¹⁵N-labelled residues at a given field strength. Although NOE values compared between different field strengths overlap within the bounds of experimental error, there is a trend toward increasing NOE at higher field. The complete set of relaxation parameter values and errors are presented in Table 3.2 on page 56.

3.2.3.2 Reduced Spectral Density Mapping

 $J(0.870\omega_H)$, calculated directly from equation 3.8, is plotted for the six ¹⁵N-labelled TM VII residues and values are compared between field strengths in Figure 3.3 on page 54. The general trend is a decrease in $J(0.870\omega_H)$ with increasing field strength, although there is overlap between values within the bounds of experimental error, and in the case of G261 $J(0.870\omega_H)$ is slightly greater at 800 MHz versus 600 MHz. From a sequential standpoint, all six ¹⁵N-labelled residues have very similar $J(0.870\omega_H)$. Using the calculated $J(0.870\omega_H)$ and experimental T_1 values, equation 3.9 can be solved for $J(\omega_N)$. $J(\omega_N)$ values calculated from 500 MHz and

600 MHz experiments overlap within the bounds of experimental error, but values calculated from 800 MHz data are clearly smaller. In terms of primary sequence, none of the six 15 N-labelled residues differs within the bounds of experimental error. Finally, experimental T_2 values and calculated $J(\omega_N)$ and $J(0.870\omega_H)$ values can be used to solve equation 3.10 for J(0). There is considerable overlap in J(0) across field strengths within the bounds of experimental error, although there is a trend toward higher values at 800 MHz. However, from a sequential standpoint, none of the six residues has a significantly different J(0) at a given field strength.

3.2.3.3 Model-Free Analysis

The most common analysis of ¹⁵N amide relaxation data for proteins and peptides is the Lipari-Szabo model-free approach where three parameters $(S^2, \tau_e, \text{ and } \tau_M)$ describe the motion of a ¹⁵N-H bond vector based on spectral density functions (i.e., equation 3.7) (6, 7). The complete model-free results are summarized in Table 3.3 on page 57. For L254, L258, and L273, AIC selection favored model five, but each fit had a highly skewed χ^2 distribution so the next most likely model was chosen. This is also preferable because model five has the most fitting parameters (four), which can increase the strength of fit independent of its true reflection of the empirical relaxation data. The AIC approach selected model four for G261, L264, and A268, which includes a chemical exchange term, $R_{\rm ex}$ —defined as a relaxation contribution from μ s-ms time scale motions (8). This is consistent with a strand of the peptide spanning from G261 to A268 that is subject to chemical exchange. G261 has a slightly lower order parameter ($S^2 = 0.65 \pm 0.02$) than the other five ¹⁵N-labelled residues $(S_{average}^2 = 0.80 \pm 0.02)$. For G261, the slightly reduced order parameter is not consistent with an elevated J(0) (Figure 3.3). Although neither J(0) or S^2 is remarkably different from those of the other five residues, it is noteworthy that chemical exchange $(R_{\rm ex})$ motions in the μ s-ms range can inflate J(0) for affected residues (88, 134):

$$J(0)_{\text{obs}} = J(0)_{\text{corr}} + \lambda R_{ex} \tag{3.12}$$

where λ is a positive scaling factor, $\lambda = (\frac{3}{2})[\frac{1}{3d^2+c^2}]$; c and d are the chemical shift and dipolar constants defined in section 3.2.2; and $J(0)_{\text{obs}}$ and $J(0)_{\text{corr}}$ are the values before and after correction for the contribution from chemical exchange, respectively. Since G261 has the largest R_{ex} value estimated from model-free analysis (1.9 ± 0.2) s⁻¹ (Table 3.3), it is certainly possible that chemical exchange can account for the discrepency of $J(0)_{\text{obs}}$ and order parameter for G261. I avoid a more detailed consideration of chemical exchange since accurate quantification requires relaxation dispersion experiments (88, 135).

3.2.4 Discussion

3.2.4.1 Relaxation Parameters: Comparing Theory And Experiment

The six 15 N-labelled residues of the TM VII peptide have similar values for all three relaxation parameters at each field strength (Figure 3.2 on page 53) suggesting similar flexibility on the ps-ns time scale along the length of the peptide. Both T_1 and T_2 follow the expected theoretical trends within experimental error for relaxation time versus field strength at the experimentally determined rotational correlation time (τ_M) of ~10 ns. Analysis of the steady-state NOE is a bit more convoluted. The predicted trend is a decrease in the NOE with increasing field strength for a τ_e in the tens of ps range as estimated from model-free analysis (Table 3.3 on page 57) coupled with the experimentally estimated τ_M . However, we generally observe that NOE increases with field strength (Figure 3.2). It is possible that the effective internal correlation times are underestimated, in which case a τ_e of 350 ps would be sufficient to account for the observed trend. This is not surprising given the low precision in the τ_e estimations from model-free analysis (Table 3.3). Low τ_e precision from model-free

analysis is especially pronounced for restricted residues ($S^2 \ge 0.8$) (121).

3.2.4.2 Reduced Spectral Density Mapping

No significant differences were observed for $J(0.870\omega_H)$, $J(\omega_N)$ or J(0) at a given field strength for the six ¹⁵N-labelled residues (Figure 3.3 on page 54), again suggesting that motions on the ps-ns time scale are similar for the tested residues. The propagated errors at the three spectral density frequencies vary considerably, and also depend on the field strength of measurement. The former result is consistent with previous NMR dynamics analyses on a series of peptides where errors varied between negligible and large on a per-residue basis at a given spectral density frequency (83). The most commonly used measure of structural flexibility in spectral density mapping is J(0), the value of the function at zero frequency. It is normally interpreted as a measure of restricted motion, with large values suggesting increased local structure, and small values consistent with flexibility (88, 83). Chemical exchange $(R_{\rm ex})$ and ¹⁵N chemical shift anisotropy (CSA) variations along the primary sequence of the peptide may contribute to errors in J(0) and may explain the deviations between field strengths we observed (Figure 3.3) for this theoretically field-independent parameter (88). Specifically, J(0) values calculated from higher field strength data are more susceptible to inflation by chemical exchange contributions to R_2 (88), and our J(0) values are generally greater using 800 MHz data (Figure 3.3). J(0) values are similar for all six ¹⁵N-labelled residues, suggesting an equal degree of motional restriction on the ps-ns time scale. The slightly reduced order parameter for G261 does not contradict its J(0) because chemical exchange can inflate the observed J(0)(88, 134). If G261 is a pivot point allowing motion of the portions of TM VII Cand N-terminal to it relative to each other, as we have previously suggested (22), the motion at this residue is most likely to be on the μ s-ms time scale. This estimate of the motional time scale is based both on the observation of a single set of exchangeaveraged chemical shifts despite extensive conformational sampling in the peptide apparent from nuclear Overhauser effect contacts (22) and on the mathematical fit of a chemical exchange term $(R_{\rm ex})$ from our model-free analysis (Table 3.3).

3.2.4.3 Correlating Structure, Dynamics, And Function

The structure of TM VII in DPC micelles is an interrupted α -helix (22). For a converged structural ensemble without discarding a significant portion (> 34%) of the NOE contacts assigned, it was necessary to employ a new dual-conformer calculation protocol (22, 29). Through parallel calculation of pairs of conformers, all NOEs were satisfied, implying extensive conformational sampling about the G261-S63 region of the TM segment. The dual-conformer protocol is equally accommodating of pairs of non-interacting conformers existing simultaneously in the ensemble vs. oligomerization. Because NOEs were almost entirely satisfied through isolated dual conformers, rather than dimer formation, TM VII was attributed to be a monomer undergoing conformational exchange (22). The TM VII peptide gave a single set of averaged chemical shifts, rather than multiple sets of independently sequentially assignable shifts implying distinct and long-lived conformations (*i.e.*, our recent structure of apelin-17 (136)). Chemical shift averaging demonstrates that interconversion between the two major conformers assumed by TM VII in micelles is rapid on the NMR time scale (~ms or faster).

Placing this in context of 15 N-backbone relaxation, the highly similar T_1 , T_2 , and steady-state NOE values imply highly similar dynamics at the ps-ns time scale along the length of the TM VII peptide. In light of both the chemical shift averaging and the lack of distinctive variations in ps-ns dynamics, conformational interconversion is therefore most likely to be in the μ s-ms regime. To produce the observed dual-conformer set of TM VII structures, this exchange must be occurring in the G261-S263 region and is consistent with a chemical exchange model being selected from model-free analysis for residues G261, L264, and A268 (Table 3.3 on page 57), with the largest $R_{\rm ex}$ parameter for G261. From these model-free results, a hypothetical

mechanism is that the N-terminal region of TM VII is undergoing relatively little μ s-ms level motion while the G261-S63 pivot point is allowing the C-terminal region containing L264 and A268 to exchange between two conformations relative to the N-terminus.

In order to consider the necessity of flexibility allowed by the break in helicity of the otherwise helical TM VII segment at residues G261-S263, I compare two sets of mutagenesis studies performed by our collaborators (for the details of the functional studies see (2, 22)). E262 is not considered in this structural-dynamic correlation analysis, given the likelihood of involvement in ion translocation (14). There is a perturbation to function with Ala mutation and almost complete loss of function with Ile mutation for the full-length NHE1 protein with mutation at F260, G261 and S263. Liu and Deber have tested the propensity for all 20 amino acids to form an α -helix in a hydrophobic environment (122, 123). Using these results, the effect of the various Ala and Ile mutations presented both previously (22) and herein can be examined in the context of a perturbation to the formation of a non-helical region. Mutation of F260, which is in the N-terminal α -helical region of TM VII, to Ala or Ile would be fairly non-perturbing in terms of secondary structure propensity and F260I reasonably conservative in terms of side-chain size; therefore, the loss of the F260 side-chain itself appears to be the critical feature of this mutation. Both G261A and G261I are relatively non-perturbing in terms of α -helical propensity in a membrane. For this position, therefore, the lack of steric constraint of a Gly residue seems likely to be the most important factor, correlating well to the break in helical structure and to the evidence for μ s-ms scale dynamics at G261. S263 is sensitive to mutation to either Ala or Ile, with mutation to either residue significantly increasing helical propensity. A good possibility is that the Ala and Ile mutants are sufficiently perturbing to local structure to extend the helical segment beginning at L264 to include S263A or S263I. This would significantly perturb both structure and dynamics in the G261-S263

region.

Interruptions in regular secondary structure have now been documented for NHE1 TM segments IV, VII, IX, and XI (22, 137, 1, 27). It will be important to assess the theme of intermediate time scale motion about a pivot point such as that predicted herein with more detailed chemical exchange information by performing relaxation dispersion experiments (88, 135). Structural and dynamics characterization of mutant TM domains which are known to significantly perturb function are also a potentially valuable tool in terms of understanding these processes. Chemical exchange is entirely consistent with the alternating-access mechanism proposed for exposure of E262 to cytosolic protons during the ion translocation cycle of NHE1, where the residue is bent away from the cytosol in certain conformations (14). An alternating-access mechanism was also proposed for the homologous NhaA protein on the basis of its crystal structure (42).

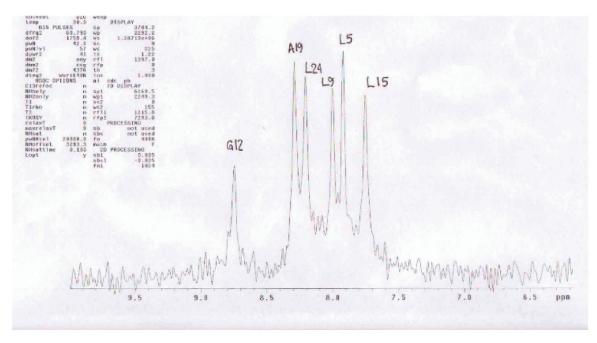

Figure 3.1: The integrity of the NHE1 TM VII sample in DPC micelles was verified by collection of a one-dimensional $^1\mathrm{H}$ - $^{15}\mathrm{N}$ NMR spectrum on a 600 MHz spectrometer (128 scans). The spectrum is consistent with results from a previous pure sample of NHE1 TM VII (not shown).

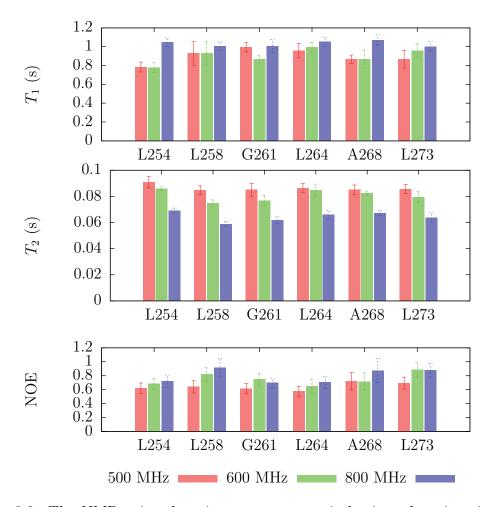

Figure 3.2: The NMR spin-relaxation parameters spin-lattice relaxation time (T_1) , spin-spin relaxation time (T_2) , and steady-state NOE are plotted for measurements at three magnetic field strengths for each of the ¹⁵N backbone-labelled positions in the NHE1 TM VII peptide construct. Each residue is numbered according to its position in full-length NHE1.

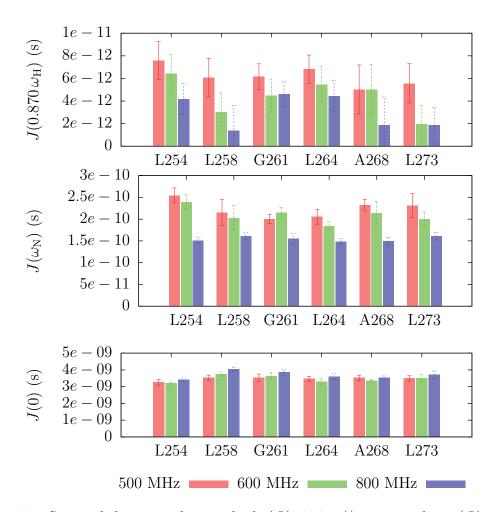

Figure 3.3: Spectral density values at high $(J(0.870\omega_{\rm H}))$, intermediate $(J(\omega_{\rm N}))$ and zero (J(0)) frequencies are shown for each of the six ¹⁵N-labelled NHE1 TM VII residues for measurements at three magnetic field strengths. The spectral densities represent the population of ¹⁵N-H bond vectors rotating at a given frequency, and the results are similar for each residue at a given field strength within the bounds of uncertainty.

Table 3.1: NMR parameters for 15 N relaxation experiments at 500, 600, and 800 MHz.

Table 3.2: The full set of longitudinal relaxation rate (R_1) , transverse relaxation rate (R_2) , and steady-state NOE ¹⁵N amide relaxation parameters for NHE1 TM VII in DPC micelles.

Chapter 4

Technicalities Of Spitz Preparation

4.1 Introduction

Spitz is a TM protein substrate of rhomboid-1 (Figure 4.1), an intramembrane serine protease localized to the Golgi apparatus in the *Drosophila* secretory pathway. Rhomboid is named for the abnormal rhomboid-shaped head skeleton observed in a Drosophila mutant (138). It was later found that rhomboid-1 cleavage of spitz is important for the release of this *Drosophila* epidermal growth factor receptor (EGFR) ligand and that proteolytic activity is controlled by Golgi compartmentalization of enzyme and controlled trafficking of substrate by another protein, Star, from the endoplasmic reticulum (ER) to Golgi (139, 140). Indeed, spitz is the principal activating ligand for Drosophila EGFR and is similar to mammalian TGF_{α} . While Star is clearly required to chaperone spitz from the ER to the Golgi, it is not involved in the actual cleavage of spitz (139). The cleavage of spitz was clearly established to occur in the Golgi and the luminal fragment is then trafficked to the plasma membrane and released for EGFR signaling. Drosophila rhomboid-1 was the first example of an intramembrane serine protease, but a number of others have since been identified across all kingdoms of life (reviewed by (10)). The sequence diversity between rhomboids in different organisms is striking, and only loose sequence requirements have been established for substrate cleavage (141). There is, however, some agreement that postulated helix-breaking residues are required in the substrate for cleavage to occur.

There are many biologically-relevant examples of rhomboid homologues. The bacterial rhomboid AarA from *Providencia stuartii* cleaves part of the twin-arginine translocase subunit, TatA, and this process is required for the release of a quorum sensing ligand (142). Although TatA oligomerizes to allow for folded bacterial proteins to exit the cell, it is not yet clear if the quorum sensing ligand is directly released by the oligomerization of TatA. Nonetheless, *P. stuartii* is an opportunistic human pathogen, and quorum sensing is involved in its antibiotic resistance (143). Futhermore, apicomplexan rhomboids can cleave cell-surface adhesins, and this appears to be important for invasion of host cells by *Plasmodium falciparum* (144), the parasite responsible for human malaria. Yeast mitochondrial rhomboids are known to regulate membrane remodelling (145). Similarly, the mitochondrial rhomboid PARL (presenilin-associated rhomboid-like) regulates remodelling of cristae and apoptosis in mice (146).

There is clearly a diverse set of rhomboid functions in different organisms, and there are likely many functions yet to be uncovered. Surprisingly, there are no rhomboid-specific inhibitors despite the fact that rhomboids are not phylogenetically related to their soluble serine protease counterparts (reviewed in (10)). Indeed, rhomboids use a Ser-His catalytic dyad unlike their soluble counterparts which require a catalytic triad involving aspartic acid (147). Furthermore, although it has been five years since the first reported rhomboid protease crystal structure, that of E. coli GlpG (4), it remains unclear how the substrate enters the active site of the protease—which is surrounded by the helices of the polytopic rhomboid. Some convincing mutagenesis work shows that GlpG TM5 is likely a substrate gate (148), consistent with the variations in TM5 position reported between several different rhomboid crystal structures (reviewed in (149)).

Most structural studies to date on the spitz-rhomboid or homologous systems have focused on the protease rather than the TM substrate. The recent crystallization of *E. coli* GlpG with an irreversible (covalent) mechanism-based isocoumarin inhibitor is a step in the right direction (150), but still does not fully address how a peptide-sized substrate can laterally enter the TM core of the enzyme. To my knowledge, there is no high-resolution structure available for a validated rhomboid substrate. With the biological incentives for understanding rhomboid proteases highlighted above, we endeavoured to produce the first high-resolution structure of a spitz TMD construct. A number of attempts at producing and purifying a variety of spitz and related TMD constructs are described in this chapter. Clearly, the peptides are not very tractable. Although it was possible to collect NMR spectra for one of the preparations (see section 4.4 on page 62), it has not been possible to solve the high-resolution NMR structure yet. Additional studies on the spitz-rhomboid system were performed using coarse-grained molecular dynamics simulations (see chapter 6 on page 191).

4.2 Solid-Phase Peptide Synthesis

My primary strategy for production of rhomboid protease substrate constructs was the use of Fmoc (9-fluorenylmethoxycarbonyl) solid-phase peptide synthesis (SPPS). Fmoc-protected amino acids, Fmoc-Lys(Boc)-Wang resin (0.57 mmol/g), Fmoc-Ile Wang resin (0.55 mmol/g), O-benzotriazole-N,N,N',N'-tetramethyl-uronium-hexafluoro-phosphate (HBTU), and 2-(1H-7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyl uronium hexafluorophosphate methanaminium (HATU) were from aapptec (Louisville, KY). Fmoc-Lys(Boc)-Wang resin (0.19 mmol/g) was from Otwo Biotech (Guangdong, China). Side chain protecting groups on Fmoc amino acids were 2,2,4,6,7-pentamethyl-dihydrobenzofuran (Pbf) for Arg; triphenylmethane (Trt) for Gln and His; tert-butyl (tBu) for Ser; and tert-butoxycarbonyl (Boc) for Lys. N,N-dimethylformamide (DMF, sequencing grade) was obtained from Fisher Scientific (Ottawa, ON). N,N-

diisopropylethylamine (DIEA) was consistently used to facilitate coupling reactions while piperidine was used for Fmoc deprotection reactions. HBTU was used as the coupling reagent for most reactions, but HATU was used for coupling with more costly amino acids (especially those with isotopic labels), and for couplings that follow the incorporation of His or Cys. For problematic coupling reactions, after several rounds of attempted coupling, an acetylation reaction with acetic anhydride was normally performed to cap unreacted sites. The Kaiser (151) and isatin (152) colourimetric tests were used to monitor the completion of reactions.

4.3 Production And Purification Of A 34-Residue Spitz TMD Construct (tr-08-1)

The Fmoc solid-phase peptide synthesis of a 34-residue construct (KRPRPM-LEKASIASGAMCALVFMLFVCLAFYLRK; designated tr-08-1) of the spitz TMD was performed using 0.6 g of Fmoc-Lys(Boc)-Wang resin (0.57 mmol/g loading). After cleavage from the synthesis resin, the crude compound was largely insoluble in a number of solvents: H_2O , trifluoroacetic acid (TFA), isopropanol, acetonitrile (ACN), and dimethyl sulfoxide (DMSO). After a few days of lyophilization in a mixture of these solvents, \sim 50 mg of crude peptide was dissolved in 3 mL of 100% TFA. The TFA solution was diluted with 50% H_2O/ACN , and a \sim 0.7 mg/mL crude solution was subjected to C3 reverse-phase high performance liquid chromatography (HPLC) (not shown). Mass spectrometry results were consistent with the presence of the target product, but the HPLC profile exhibited substantial impurities.

Many HPLC runs were performed and DTT treatment seemed to improve the traces, so disulfide bond formation may have contributed to the reduced solubility and tractability of the peptide. However, there were persistent inconsistencies in peak elution times in matching runs and we decided to produce the same peptide construct with Cys residues replaced by Ser in an attempt to improve handling (section 4.4 on

page 62). In retrospect, I think it would have been worth performing several rounds of crude lyophilization in the presence of excess H₂O, as this approach often improved the solubility of subsequent synthetic spitz constructs.

4.4 Production And Purification Of A 34-Residue C→S Spitz TMD Construct (tr-08-2)

The substantial problems with peptide handling experienced working with the TR-08-1 construct (section 4.3 on page 61) may relate to the formation of disulfide bonds and oligomerization. I repeated the SPPS procedure using Ser in place of both Cys residues. The new construct, labelled TR-08-2, was cleaved from the resin to yield a yellow gel-like crude product that dissolved in 25% $\rm H_2O$, 25% ACN, 50% formic acid. Lyophilization over several days with excess water produced a white powder. Initial electrospray ionization mass spectrometry (ESI-MS) results were consistent with the presence of 3+, 4+, 5+, and 6+ charged species of the \sim 3828 g/mol peptide (not shown).

The purity of the crude sample was further assessed by C18 analytical HPLC (Figure 4.2 on page 74) and there were a number of species present. The MALDI-MS results (not shown) were consistent with the elution of product in fraction 7 (30-35 minutes). TR-08-2 samples were concentrated by optimizing the solvent—optimal reconstitution was achieved in 60% deionized water (DI-H₂O), 40% ACN. After multiple attempts at HPLC gradient optimization for purification (not shown), one of the most promising fractions produced an encouraging MALDI-MS result (Figure 4.3 on page 75). We were reasonably satisfied with the purity demonstrated by this MALDI spectrum (although in retrospect I'd be more concerned about the low molecular weight species), and decided to purify the entire ~19 mL crude stock. At the time we were limited to a 250 μ L sample loop, and I completed 76× 48-minute HPLC runs to purify the crude (see Figure 4.4 on page 76 for a representative HPLC trace).

The pooled TR-08-2 samples produced using the above workflow were lyophilized and further HPLC purification was performed (Figure 4.5 on page 77). Curiously, the MALDI-MS results for fraction 1 (Figure B.35 on page 251) and fraction 2 (Figure B.36 on page 252) similarly reflected a relatively pure sample with major species ~ 3830 g/mol, and the results were also verified by ESI-MS (not shown). Thus, both fractions were collected via many additional rounds of HPLC purification, yielding 0.8 mg and 2.4 mg of fractions 1 and 2 respectively. An NMR sample was prepared with the following composition: 1 mM DSS, 95% $\rm H_2O/5\%$ D₂O, ~ 75 mM DPC-d₃₈, $\sim 260~\mu$ M peptide (TR-08-2 fraction 1), and pH 5. A matching sample (but slightly more dilute at $\sim 100~\mu$ M fraction 1, 32 mM DPC) was used for circular dichroism spectropolarimetry (Figure 4.6 on page 78). The peptide appears to be α -helical, and qualitatively similar results were obtained for a very dilute solution of fraction 2. However, TOCSY (total correlation spectroscopy) and HSQC (heteronuclear single quantum correlation) NMR experiments on a 500 MHz spectrometer had insufficient signal, and the described sample may have been too dilute (not shown).

A more concentrated NMR sample was made with TR-08-2 fraction 2 with the following composition: 0.96 mM peptide, ~75 mM DPC-d₃₈, 95% H₂O/5% D₂O, 1 mM DSS, and pH 5. Although reasonable signal/noise could not be obtained on a 500 MHz spectrometer, high quality NMR spectra were obtained on a 700 MHz magnet (fitted with a cryogenically cooled probe). 2D NOESY (200 ms mixing time, Figure 4.7 on page 79), TOCSY (Figure 4.8 on page 79), and natural abundance ¹³C-HSQC spectra were used for resonance assignment. However, as demonstrated in the TOCSY caption, there is substantial resonance overlap and after several weeks of attempted assignment it was deemed unlikely that the homonuclear NMR data would suffice for structure determination. The next step was to produce a construct with isotope labels to facilitate resonance assignment (section 4.5 on page 64).

4.5 Production And Purification Of A 21-Residue Spitz TMD Construct (tr-09-1)

A 21-residue spitz TMD peptide construct was designed as outlined in Figure 4.9 on page 80. The Fmoc solid-phase peptide synthesis of this construct (designated tr-09-1) was performed with 0.6 g of Fmoc-Lys(Boc)-Wang resin (0.57 mmol/g) and includes the incorporation of selective fractional ¹⁵N backbone labels. Predicting the isotopic mass of the major expected product requires a 'tree-branch' analysis approach (Figure 4.10 on page 81). The latter analysis suggests that major products will incorporate 4-5 ¹⁵N backbone labels. Accounting for the natural abundance of ¹³C and the incorporation of an additional proton in matrix-assisted laser desorption/ionization (MALDI) mass spectrometry, the expected mass of the product is ~2249-2250 g/mol. I wrote an internet-accessible python program (available at: http://129.173.89.133/cgi-bin/isotope_cgi.py) for performing these fractional isotope calculations and the underlying code is included in module A.1 on page 206.

As anticipated from work with previous spitz TMD constructs, there were substantial problems with the solubility of tr-09-1. None of the following solvents could dissolve the crude peptide after cleavage from the resin: ACN/H₂O mixtures, methanol, isopropanol, chloroform, hexane, or DMSO. One possibility is that disulfide crosslinking reduces the solubility of the crude peptide, but a 70% H₂O, 30% ACN, 200 mM dithiothreitol (DTT) mixture with trace TFA could not dissolve the product, even after treatment at 80 °C. While the crude peptide was also insoluble in 50% H₂O/50% TFA, it was finally possible to dissolve the crude peptide in a 100% TFA solution. However, the lyophilization product did not have an improved appearance or consistency—it was a thick, dark yellow gel combined with dark yellow plastic-like flakes. MALDI-MS of the crude sample was consistent with two products in the target mass range—one missing the N-terminal K residue, and the other an almost perfect match to the expected isotopic mass calculated above (Figure 4.11 on page 82).

Having confirmed the presence of the desired product in the crude mixture, we decided to lyophilize the gelatinous crude sample in a large volume of $\rm H_2O$ in an attempt to remove TFA and other undesirable impurities which may have persisted from the synthesis, cleavage, and lyophilization in other solvents. After several rounds of lyophilization with excess water, the crude sample was a mixture of white and yellow powder. The new crude sample was successfully dissolved in a solution with final composition as follows: ~ 1.5 mg/mL crude peptide in 1 mL of 50% $\rm H_2O$ / 50% ACN, 200 mM DTT. The purity of the sample was assessed by HPLC as detailed in Figure 4.12 on page 83. Lyophilized fractions from the crude HPLC run were reconstituted in 50% $\rm H_2O/ACN$, either with or without 200 mM DTT (1 hour treatment), and then diluted two-fold with α -CHC matrix. MALDI results were consistent with elution of the product between 18-30 minutes on the HPLC trace (see summary Table 4.1 on page 102 and selected MALDI mass spectra starting with Figure B.1 on page 217).

The apparently broad elution of the desired product, along with low molecular weight impurities, over a 12 minute HPLC window may result from the rather large 6 minute fraction collection times. Therefore, an HPLC run using the same ACN gradient was repeated with a similar preparation of crude, but using narrower 1 minute fraction collection windows. A broad mass of peaks was again apparent between 18-30 minutes (Figure 4.13 on page 84), and MALDI-MS on the 12×1 minute fractions between 18-30 minutes revealed some promising candidates for additional purification (see summary Table 4.2 on page 103 and selected MALDI spectra starting with Figure B.5 on page 221). While the persistence of low molecular weight impurities and the nearly continuous co-elution of the ~2121 g/mol species (missing the N-terminal K) along with the desired product at ~2250 g/mol should be noted, fraction 5 (22-23 minutes) stands out as the most promising with a favorable 2250:2121 species ratio (assuming a similar MALDI ionization potential).

The MALDI-MS of the most promising C3 (HPLC) column-purified TR-09-1 frac-

tion (#5) contains impurities including a major species at ~1096 m/z and the truncated product at ~2121 m/z (Figure B.5 on page 221). In an attempt to improve separation, I repeated the same ACN gradient on a C18 semi-preparative HPLC column with the C3 column-purified fraction #5 as starting material (Figure 4.14 on page 85). A promising set of peaks eluted at ~24-26 minutes from the C18 column, and the run was repeated to collect 15 second fractions in the region of interest (Figure 4.15 on page 86). The best sample purity yet was achieved in fraction #5 from the C18 column, with the target MALDI peak dwarfing the truncated product and most low molecular weight species (see summary Table 4.3 on page 103 and selected MALDI spectra starting with Figure B.11 on page 227).

For the sake of time and yield, it is desirable to avoid a 2-column HPLC purification scheme as described above. Therefore, I loaded a crude TR-09-1 sample directly to the C18 semi-preparative column to assess the HPLC separation that can be achieved (Figure 4.16 on page 87). The run was repeated (Figure 4.17 on page 88) with collection of fractions near the window of optimal purification observed for the C18 column in the two-part purification scheme. It is encouraging that one of the fractions from this single-column purification scheme exhibited the target product as the major peak (see summary Table 4.4 on page 104 and selected MALDI spectra starting with Figure B.15 on page 231). The purest fraction was offset by ~15 seconds relative to the optimal elution in the two-part scheme. The delay may reflect differences in sample viscosity/composition (i.e., C3 column-purified sample would have substantially less impurities than the direct load of crude).

At this stage, it appears that a C18 HPLC column may provide a route to TR-09-1 purification with an optimized ACN gradient. However, I first wanted to verify the purity of fraction # 5 (from the two-column purification scheme) on a C18 analytical column–since this fraction was the purest I had obtained to date and it is desirable to assess the point at which a relatively pure sample elutes from a C18

column. The results were confounded by an impurity present on the C18 analytical column (Figure 4.18 on page 89), and there was no clear candidate peak for elution of the relatively pure sample. Instead of simply repeating the method, I designed a slower ACN gradient for the C18 analytical column in an attempt to achieve better separation of TR-09-1 crude (Figure 4.19 on page 90). However, there were peaks on the tail of the solvent front so I decided to switch to a more conservative starting % ACN and collected fractions for some reasonably well-resolved HPLC peaks near the estimated ~48% ACN elution point for TR-09-1 (Figure 4.20 on page 91). Unfortunately, MALDI-MS results did not show evidence of TR-09-1 in any of the analytical fractions (not shown). I reloaded the fractions to the C18 analytical column and the results did not convincingly demonstrate that I had in fact captured the target peaks with the assumed ~97.5 second delay at 0.48 mL/min (not shown).

Assured delay by HPLC re-calibration allowed me to return to the original challenge—purification of TR-09-1. I decided to aim for bulk purification of TR-09-1 on a C18 semi-preparative column since the C18 results had generally been better than C3, and because another group reported successful purification of similar spitz TMD constructs using a C18 column (153). The entire remaining TR-09-1 stock was dissolved in ~15 mL of 50% ACN/H₂O, 0.1% TFA, 156 mM DTT solution. The mass of crude prior to dissolution was not known, but the latter solution was quite viscous. The first two bulk purification test runs on the C18 semi-preparative column are shown in Figure 4.21 on page 92. The fractions were collected in too narrow a time window in the first run based on the MALDI results (summarized in Table 4.5 on page 104 and see selected MALDI spectra starting with Figure B.19 on page 235). I shifted the fraction collection to a later time window (on the basis of crude viscosity and the latter MALDI results) in the second run, and while the product was more prominent in some of the fractions, some product was present in virtually all of the fractions over the 7 minute collection window (see summary Table 4.6 on page 105 and selected

MALDI spectra starting with Figure B.21 on page 237). The breadth of product elution based on MALDI results is not surprising given the outrageously broad HPLC profiles for crude TR-09-1.

The 2-100% ACN gradient used for the bulk purifications above may ramp too rapidly and result in incomplete separation, especially in the context of a concentrated sample. I tried a set of more conservative gradients in C18 semi-preparative HPLC purifications of the crude—starting at 40% ACN (Figure 4.22 on page 93) or 30% ACN (Figure 4.23 on page 94). Depressingly, TR-09-1 eluted over (practically) the full 26 minute range of collected fractions from the replicate starting at 40% ACN (see summary Table 4.7 on page 105 and selected MALDI spectra starting with Figure B.24 on page 240). Expansion of the collection window in the following run (starting at 30% ACN) revealed a 42 minute elution window (see summary Table 4.8 on page 106 and selected MALDI spectra starting with Figure B.26 on page 242). Some fractions were promising, but this is clearly not a desirable separation.

The ninth fraction (Figure B.26 on page 242) from the HPLC run detailed in Figure 4.23 (page 94) is promising despite the presence of the impurity at ~1096 m/z. I repeated this HPLC gradient for bulk purification of several mL of crude TR-09-1, collecting the equivalent of the ninth fraction and also collecting subsequent eluent up to 52 minutes because of the broad elution profile described above. A subset of these purification HPLC runs are compared with the original run in Figure 4.24 on page 95. All remaining TR-09-1 crude was purified in this fashion. However, it was not possible to achieve purification of sufficient material to perform NMR spectroscopy after several additional rounds of purification (not shown).

4.6 Production And Purification Of A 16-Residue TatA TMD Construct (tr-10-2)

P. stuartii TatA is a substrate of the rhomboid homologue AarA and I targeted a

TM portion of TatA for manual solid-phase peptide synthesis because of the demand on our automated synthesizer and the lack of success producing spitz constructs in an automated context. The Fmoc-based synthesis of the 16-residue TatA construct (ESTIATAAFGSPWQLI), designated TR-10-2, is based on a reported manual synthesis procedure (154) and was produced starting with 100 mg of Fmoc-Ile Wang resin (0.55 mmol/g). Remarkably, all of the colourimetric tests for completion of reactions were successful. The MALDI spectrum of the crude sample reconstituted in ACN produced a promising result that includes prominent peaks for the Na⁺ and K⁺ product adducts (starting with Figure 4.25 on page 96).

To further characterize the purity of the crude TR-10-2 preparation and to assess the prospects for separation, I performed C18 analytical HPLC on the sample (Figure 4.27 on page 98 and Figure 4.28 on page 99). The results were encouraging, with a dominant peak in the traces at 210 nm and 280 nm—the latter consistent with the presence of a W residue in the desired product. Furthermore, the target product was only present in two fractions near the expected elution time of the major peak (see MALDI summary Table 4.9 on page 107 and representative MALDI spectra starting with Figure B.33 on page 249). Impurities persist in the promising fractions but this is not surprising given the width of the HPLC collection windows. Although several attempts were made to collect higher resolution HPLC fractions in the region of interest, a number of problems with HPLC plumbing and possible contamination of HPLC solvents were highly problematic (not shown). Nonetheless, I think this particular TatA construct and manual synthesis are both promising ideas for the production of a spitz homologue.

4.7 Production Of A 37-Residue Gurken TMD Construct (tr-10-1)

Gurken is another *Drosophila* substrate of Rhomboid, and I attempted automated

solid-phase peptide synthesis of a 37 residue construct of gurken (designated TR-10-1) based on the construct outlined in (141). I incorporated a number of partial ¹⁵N-backbone isotope labels (KKRKV[50]RM[50]A[50]HIV[50]F[25]SF[20]PV[50]L[50]-LM[25]LSSL[15]YVL[25]F[10]A[75]A[100]VF[25]ML[50]RKKK, with label % following residues) during the synthesis, which used 0.7 g of Fmoc-Lys(Boc)-Wang resin (loading of 0.19 mmol/g). Colourimetric tests for completed reactions were often not successful, and it is therefore not surprising that crude peptide MALDI-MS characterization did not exhibit any prospective product peaks (not shown). It is also noteworthy that the target product mass ~4405 g/mol is calculated using a procedure similar to that outlined in Figure 4.10 on page 81 for fractional isotope incorporation.

4.8 Production And Purification Of A Spitz Construct By Expression In *E. coli*

Clearly it is difficult to produce spitz TMD constructs by SPPS, and purification by HPLC is even more problematic. Overexpression of a spitz TMD construct in *E. coli* allows for the incorporation of a hexahistidine tag for Ni-affinity purification, a FLAG tag for affinity chromatography, and does not involve the production of truncated products with similar chemical and physical properties (which is observed in SPPS because of failed reactions). Thus, there are options to circumvent HPLC purification or at least simplify the work-up by avoiding truncated species.

A 2.7 mg crude yield was obtained by expression of the construct outlined in Figure 4.29 on page 99 and subsequent Ni-affinity purification. C3 semi-preparative HPLC assessment of the crude produced a promising trace (Figure 4.30 on page 100), and ESI-MS characterization of the major peak ~26 minutes was consistent with the mass of the (N-terminal Met-deficient) unlabelled product (not shown). However, subsequent matching HPLC runs were not consistent, and expression of the ¹³C, ¹⁵N-labelled construct resulted in an extremely poor yield.

A number of expressions were attempted with different strategies for target protein isolation (*i.e.*, use of inclusion bodies), but there were always problems with sample solubility and the apparent presence of oligomers. One MALDI-MS result confirmed that $\sim 50\%$ ¹⁵N incorporation was achieved because of the (accidental) exposure of bacteria to both labelled and unlabelled nutrient sources (Figure 4.31 on page 101). In subsequent spitz expressions there were persistent problems with the presence of dimers, which could not be disrupted by exposure to 8 M urea and/or the reducing agents DTT, TCEP, or β -mercaptoethanol (see representative Figure 4.32 on page 102). Furthermore, MALDI and SDS-PAGE results were both consistent with the formation of higher order oligomers, and this may account for inconsistent elution times in matching HPLC runs. For now, spitz expression constructs are not any more tractable than constructs produced by SPPS and the yields are very low for isotope-labelled expression employing minimal media.

4.9 Conclusions

In this chapter I've described several different strategies and constructs for the production of a spitz or homologous rhomboid substrate with the ultimate objective of determining a high-resolution NMR structure. Although the latter goal was not achieved, it is certainly clear that the production and purification of these TMD constructs is extremely challenging. In light of the difficulties I had assigning resonances in homonuclear spitz TMD NMR spectra (see section 4.4 on page 62), I would strongly suggest that incorporation of isotope labels will be important for future efforts. It is still not clear if cysteine residues are forming disulfide bridges responsible for the extensive oligomerization issues reported in section 4.5 (page 64), but it is not necessarily a bad idea to substitute with Ser as described for the TR-08-2 construct.

It is particularly disturbing that successful HPLC purification of similar spitzbased TMD constructs was reported on a C18 column with no apparent difficulties (153). I have some concern that I often overloaded the column because of the broad traces that were often observed. Conversely, the poor solubility of the samples largely excluded the possibility of loading very high concentrations of crude, but may also account for in-column retention/precipitation. Furthermore, it can hardly be considered desirable to further dilute a sample that required 76× 48-minute HPLC runs for purification (section 4.4 on page 62).

Frustrated by the poor peptide tractability described in this chapter, my remaining spitz-rhomboid studies were performed *in silico* with coarse-grained molecular dynamics simulations (chapter 6 on page 191).

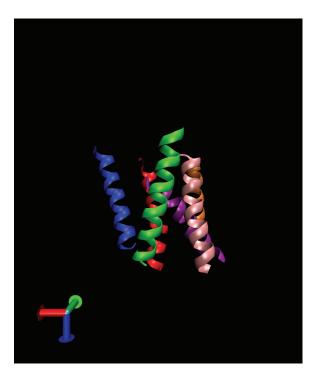

Figure 4.1: A cartoon representation of the TM segments from the ecGlpG structure (PDB: 2IC8; (4)). The top of this representation would represent the extracellular environment, the loops between helices have been excluded, and helix colouring follows the scheme: TM 1 (dark blue), TM 2 (red), TM 3 (green), TM 4 (purple), TM 5 (orange), TM 6 (pink). Note that TM 4, which includes the catalytic serine residue, is protected from the exterior of the protein by the ring of TM helices.

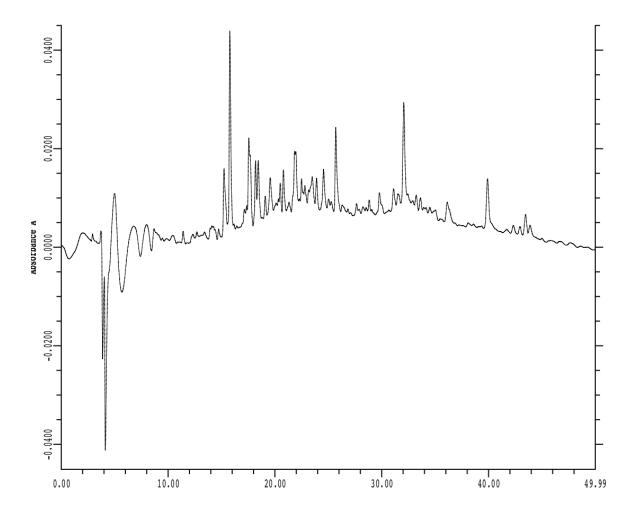

Figure 4.2: 30 μ L of a crude TR-08-2 preparation was loaded to a C18 analytical HPLC column and subject to a 0.8 mL/min gradient: 1) 2% ACN pre-run, 2) +2%/minute ACN up to 100%. Fractions were collected in 5-minute windows between 0 and 50 minutes and this trace is monitored at 210 nm. A preceding blank run with DI-H₂O did not reveal any substantial column-retained impurities (not shown).

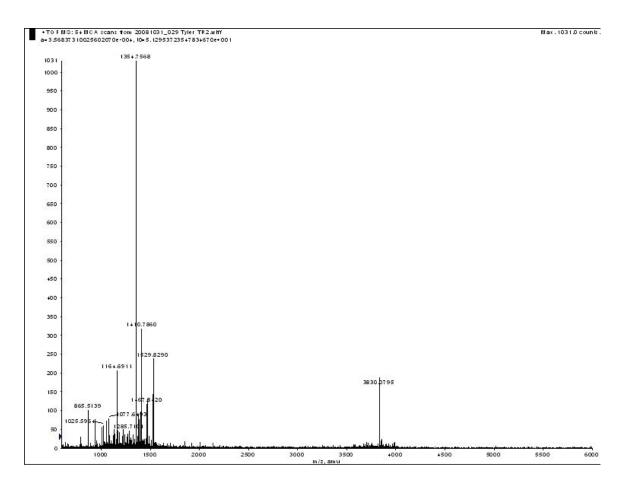

Figure 4.3: The most promising TR-08-2 fraction following several iterative rounds of HPLC optimization produced this MALDI spectrum with a clear candidate peak for the target product ~ 3830 m/z with the monoisotopic theoretical mass ~ 3828 g/mol. There do, however, appear to be some low molecular weight impurities.

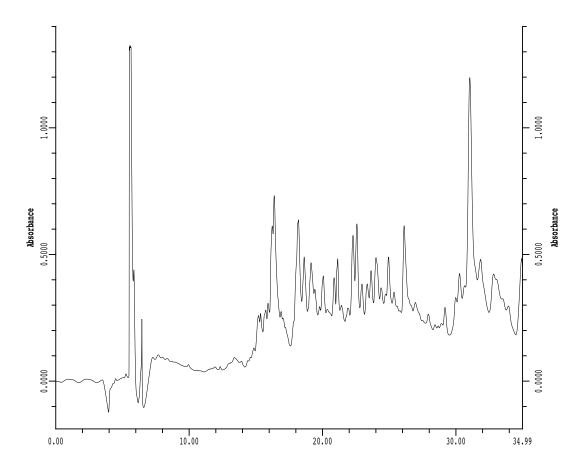

Figure 4.4: This is one of the 76 representative TR-08-2 bulk purification HPLC runs monitored at 210 nm. For each replicate, I collected between 28.5 and 32.3 minutes based on the MALDI results in Figure 4.3 on page 75 for a matching run. The gradient starts at 2% ACN and ramps by 2%/minute.

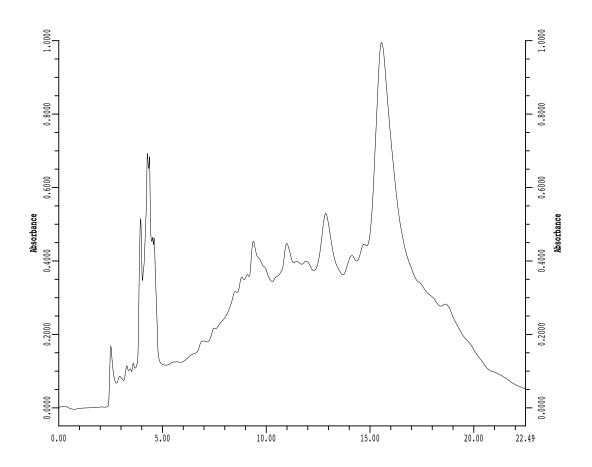

Figure 4.5: Fractions collected as detailed in Figure 4.4 (page 76) were subjected to additional semi-preparative HPLC purification and this is a representative trace monitored at 210 nm. Two fractions were collected between 12.2-14.2 minutes (fraction 1) and 14.8-16.6 minutes (fraction 2).

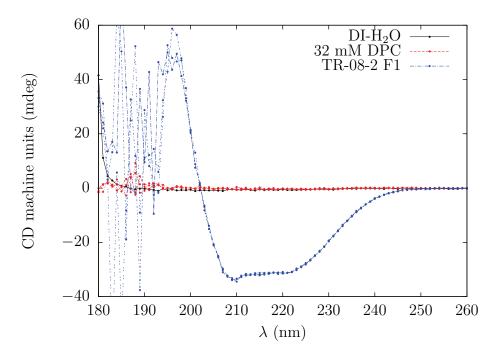

Figure 4.6: Circular dichroism (CD) spectropolarimetry was performed in triplicate for TR-08-2 preparations (100 μ M peptide, 32 mM DPC, pH 5) and a 32 mM DPC control solution at matching pH. A single blank run was also performed with deionized water. Measurements were collected at 37°C with a 20 nm/min scan rate through a 1 mm path length cell. Measured dips near 208 nm and 222 nm are characteristic of α -helical secondary structure.

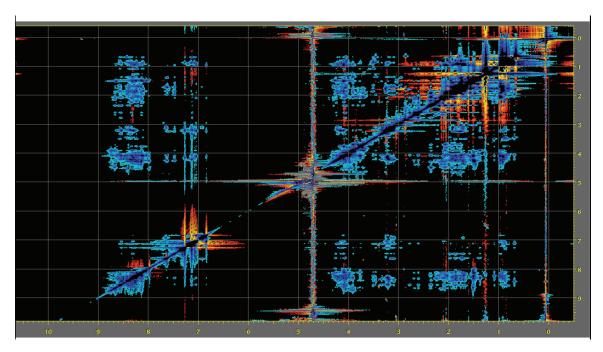

Figure 4.7: Overview of 2D ¹H-¹H NOESY (200 ms mixing time) collected for TR-08-2 on a 700 MHz magnet fitted with a cold probe. Water suppression was performed with excitation sculpting, and the spectrum was collected at 310.15 K.

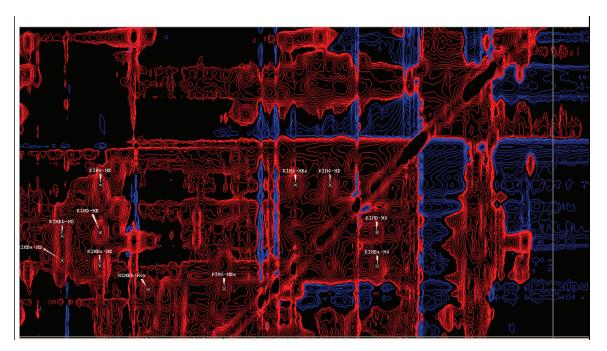

Figure 4.8: A zoom-in view of 2D 1 H- 1 H TOCSY collected for TR-08-2 on a 700 MHz magnet fitted with a cryogenically cooled probe. Water suppression was performed with excitation sculpting, and the spectrum was collected at 310.15 K. Although some assignments are visible in this caption, it is also clear that there is substantial resonance overlap.

KRPRPMLEKASIASGAMSALVFMLFVSLAFYLRK KEKASIASGAMCALVFMLFV KEKASIASGAMCALVFMLFVK

Figure 4.9: Comparing spitz TMD constructs for solid-phase peptide synthesis. The 34-residue construct with $2 \text{ Cys} \rightarrow \text{Ser}$ substitutions (top) was problematic for structure determination by NMR spectroscopy. The middle construct is known to be cleaved by a Rhomboid homologue and was successfully produced by solid-phase peptide synthesis by another group (153). I produced and purified the bottom 21-residue construct because of its similarity to the published construct.

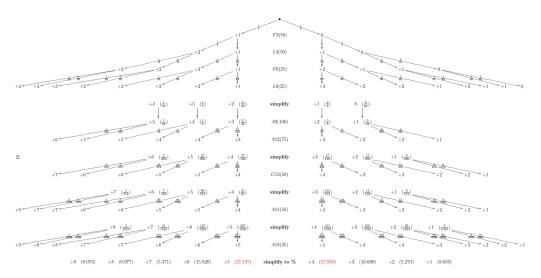

Figure 4.10: There are nine 15 N fractional selective isotope label positions in the tr-09-1 construct, and properly predicting the adjustment to the monoisotopic mass requires a 'tree-branch' probability approach as outlined here. The coupling amino acid (proceeding $C \rightarrow N$ as synthesized) and the isotope % are both indicated near the middle of the row that results from a given coupling. The arrow or parenthetical fractions indicate the proportion of all peptide species that have the resulting atomic mass adjustment (ignoring impurities that form from failed reactions). It is clear that between 4 and 5 atomic mass units should be added to the predicted monoisotopic mass to obtain the most abundant 15 N-enriched species.

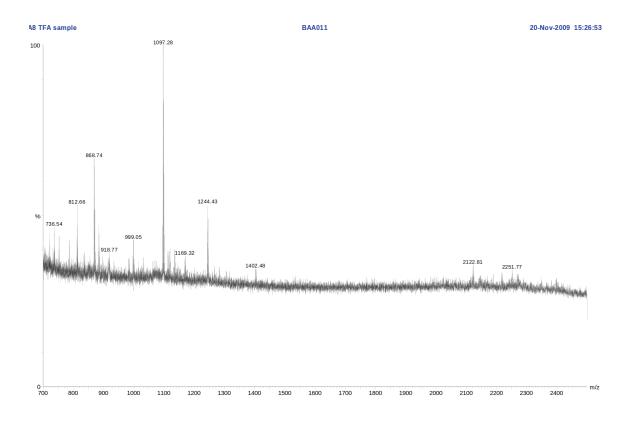

Figure 4.11: A 2.9 mg/mL crude TR-09-1 solution in 100% TFA was diluted with a MALDI matrix solution, and 1 μ L was spotted to a MALDI plate. The mass spectrum was captured in reflectron mode. The peak at ~2252 m/z is consistent with the predicted mass of the desired product while the peak at ~2123 most likely corresponds to the desired product missing the N-terminal K residue.

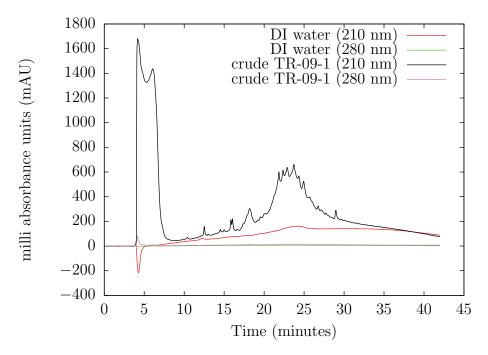

Figure 4.12: 1 mL of 1.5 mg/mL TR-09-1 crude peptide in 50% H₂O / 50% ACN, 200 mM DTT, was loaded to a C3 RP-HPLC semi-preparative column and monitored at 210 nm and 280 nm using a gradient that proceeded from 2-100% ACN in 40 minutes, followed by 100-2% ACN in 2 minutes. The blank was an equivalent volume of deionized water (DI-H₂O). Seven fractions from the crude peptide run were collected in six minute windows—F1 (0-6 minutes), F2 (6-12 minutes), F3 (12-18 minutes), F4 (18-24 minutes), F5 (24-30 minutes), F6 (30-36 minutes), F7 (36-42 minutes). The HPLC dead time at 3 mL/minute is \sim 28 seconds.

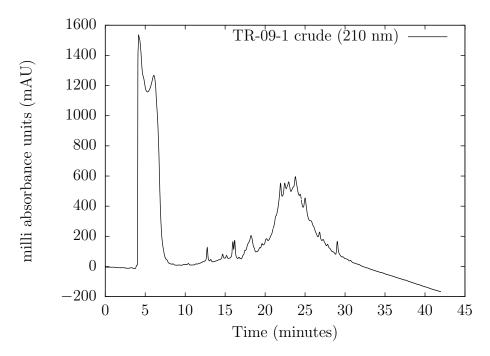

Figure 4.13: 1 mL of a 1.9 mg/mL TR-09-1 crude solution dissolved in 50% H₂O/ACN was treated with 200 mM DTT for 1 hour and loaded to a C3 semi-preparative column. The gradient and flow rate match the conditions detailed in Figure 4.12 on page 83, but in this case narrower 1 minute fractions were collected between 18 and 30 minutes run time. There were no substantial impurities in a preceding blank run with 1 mL of deionized water (not shown).

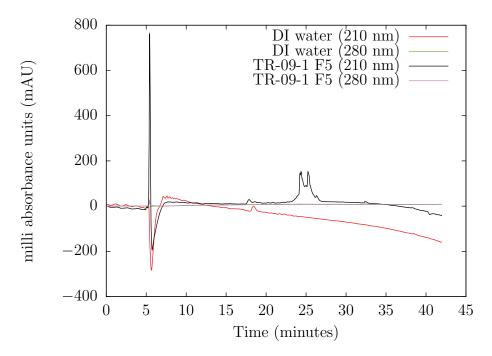

Figure 4.14: 1 mL of a C3 HPLC column-purified fraction (#5) from the run detailed in Figure 4.13 (page 84) was loaded to a C18 semi-preparative HPLC column and elution was monitored at 210 nm and 280 nm during a 3 mL/min gradient involving 2-100% ACN in 40 minutes followed by 100-2% ACN in 2 minutes. A matching volume of deionized water was used as a blank in a preceding HPLC run with the same gradient and flow rate.

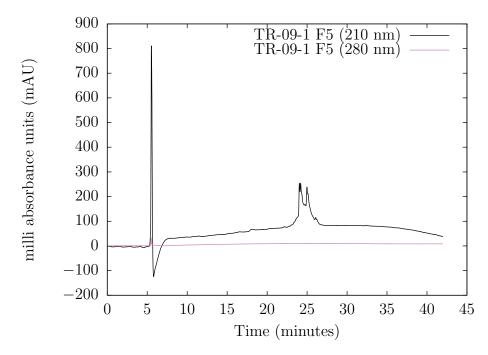

Figure 4.15: A repeat of the C18 semi-preparative HPLC run involving TR-09-1 fraction #5 (from a C3 column) as detailed in Figure 4.14 on page 85. However, in this case 8×15 second fractions were collected starting at 24:16 run time. A preceding blank run with a matching volume of deionized water did not reveal any substantial impurities (not shown).

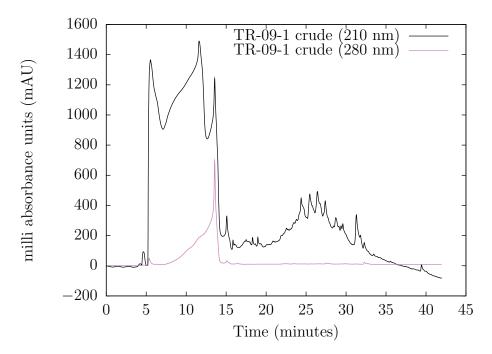

Figure 4.16: 1 mL of 1.3 mg/mL TR-09-1 crude sample in 50% H₂O/ACN and 200 mM DTT was loaded to a C18 semi-preparative column and subjected to the same method described in Figure 4.14 on page 85. A matching volume of deionized water was used in a preceding blank run with no substantial impurities present (not shown).

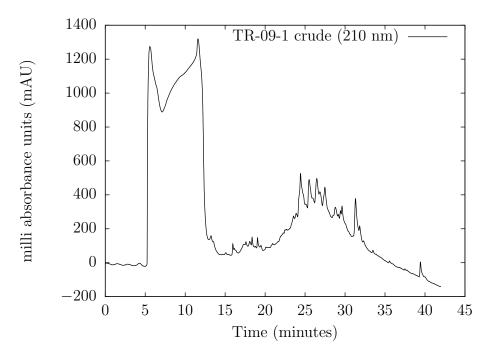

Figure 4.17: 1 mL of 2.1 mg/mL crude TR-09-1 in 50% H₂O/ACN and 200 mM DTT was loaded to a C18 semi-preparative column in a repeat of the run described in Figure 4.16 (page 87), but in this case three fractions were collected to match the promising results from a C18 column summarized in Table 4.3 (page 103): F1 (25:01-25:16), F2 (25:16-25:31), and F3 (25:31-25:46). A matching volume of deionized water was used to confirm the absence of major column impurities in a preceding blank run.

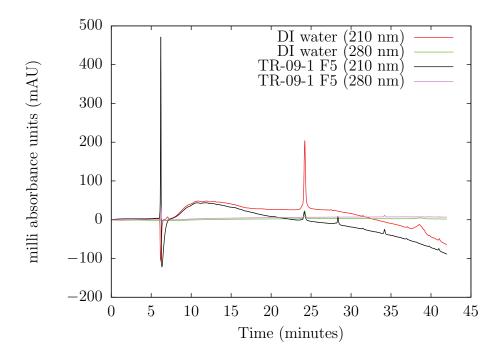

Figure 4.18: 20 μ L of the purest TR-09-1 fraction (# 5 from the two-column HPLC purification scheme) was loaded to a C18 analytical column and subject to an ACN gradient at 0.48 mL/min: 2-100% ACN in 40 minutes, followed by 100-2% ACN in 2 minutes. A matching volume of deionized water was used as a blank in a preceding run, and unfortunately a residual impurity confounds the results of the test trace.

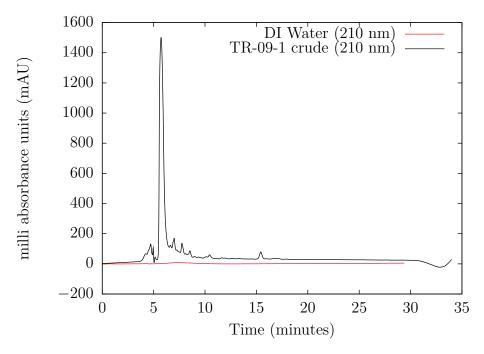

Figure 4.19: A 0.8 mg/mL preparation of TR-09-1 crude in 50% $\rm H_2O/ACN$ and 200 mM DTT was loaded to a C18 analytical column using a 20 $\rm \mu L$ sample loop. The method consisted of a 0.48 mL/min flow rate and a multi-step gradient: 1) Start at 53.9% ACN, 2) 53.9%-66.15% ACN from 0-25 minutes, 3) 66.15%-100% ACN from 25-27 minutes, 4) 100%-53.9% ACN from 27-28 minutes. The peak between 15-16 minutes on the crude trace was collected assuming a ~97.5 second delay based on the flow rate and system plumbing.

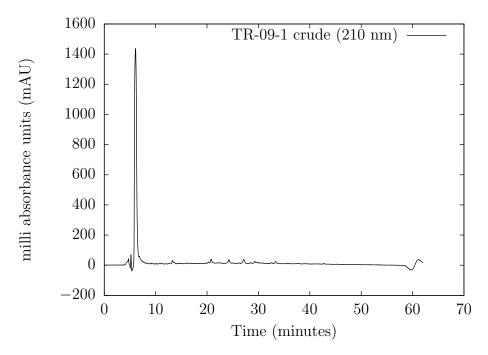

Figure 4.20: The crude TR-09-1 preparation described in Figure 4.19 (page 90) was again loaded to a C18 analytical column using a 20 μ L sample loop, but in this case using a more conservative gradient (still at 0.48 mL/min): 1) 40% ACN pre-run, 2) 40%-66% ACN in 53 minutes, 3) 66%-100% ACN in 1 minute, 4) 100%-40% ACN in 1 minute, 5) Continue monitoring run until ~62 minutes. Three sets of peaks (20-22 minutes, 23-25 minutes, 26-28 minutes) were collected assuming a ~97.5 second delay at this flow rate. A preceding blank run with deionized water demonstrated an absence of impurities on the column (not shown).

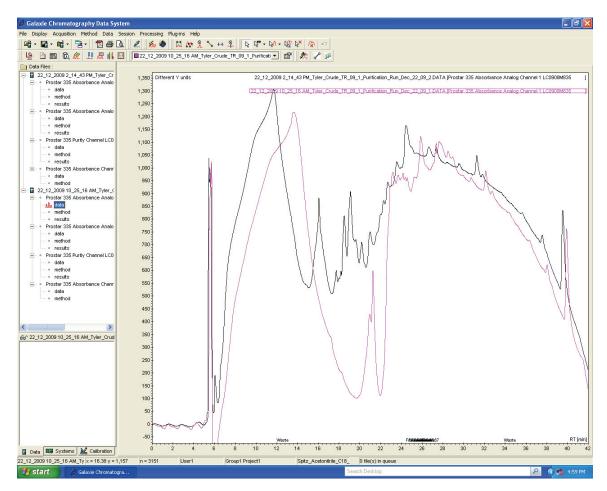

Figure 4.21: The first (pink) and second crude TR-09-1 bulk purification runs monitored at 210 nm. In both cases, 1 mL of crude (dissolved in 50% H₂O/ACN, 0.1% TFA, 156 mM DTT) was loaded to a 2mL sample loop (bottom injector) and subject to a 3 mL/min gradient on a C18 semi-preparative column similar to those described for previous C18 purifications. 7×15 second fractions were collected between 25:10-26:55 from the first replicate, and 14×30 second fractions were collected between 26:55-33:55 from the second replicate.

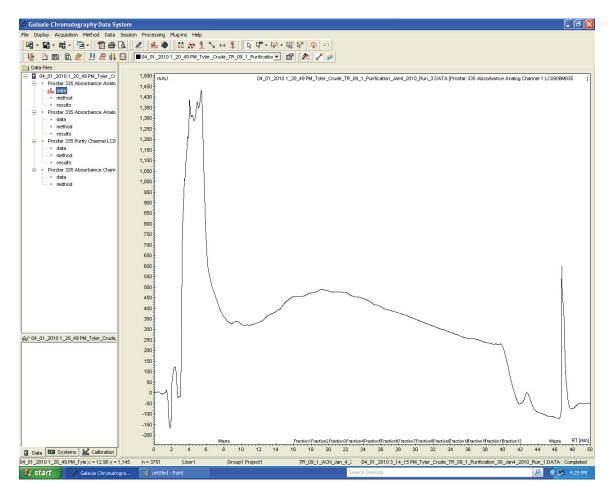

Figure 4.22: $\sim 500~\mu L$ of crude TR-09-1 was loaded to a C18 semi-preparative HPLC column via a 2 mL sample loop (bottom injector). The 3 mL/min gradient involved a few steps: 1) 40% ACN pre-run, 2) 40-75% ACN in 35 minutes, 3) 75-100% ACN in 1 minute, 4) hold 100% ACN for 5 minutes, 5) 100-40% ACN in 1 minute. 2 minute fractions were collected between 16-42 minutes. This trace is monitored at 210 nm, and a matching run with deionized water demonstrated an absence of column-retained impurities.

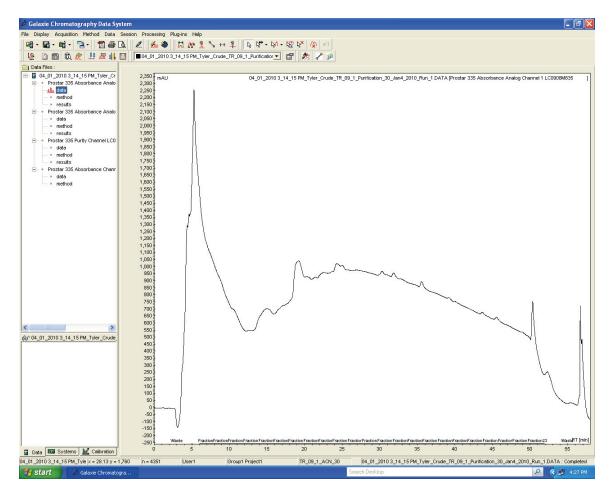

Figure 4.23: 1 mL of crude TR-09-1 was loaded to a C18 semi-preparative HPLC column via a 2 mL sample loop (bottom injector). The 3 mL/min gradient was modified from the previous run (Figure 4.22 on page 93) to start at a lower % ACN: 1) 30% ACN pre-run, 2) 30-75% ACN from 0-45 minutes, 3) 75-100% ACN from 45-46 minutes, 4) hold 100% ACN from 46-51 minutes, 5) 100-30% ACN from 51-52 minutes. This trace is monitored at 210nm.

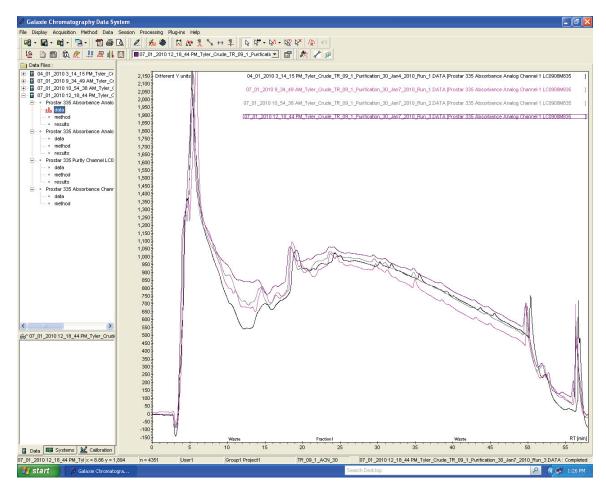

Figure 4.24: 1 mL of crude TR-09-1 was loaded to a C18 semi-preparative HPLC column and subjected to the same gradient described in Figure 4.23 on page 94. Based on the latter (original) HPLC run, the new purification runs targeted collection of the promising fraction that elutes between 22-24 minutes, but the remaining eluent up to 52 minutes was also collected because the product exhibits a very broad elution profile (see Table 4.8 on page 106). The 210 nm traces shown here compare the original HPLC run (in black) with the more recent bulk purifications. Unfortunately, the more recent runs accidentally employed a 1 mL sample loop instead of the 2 mL loop used in the original run, causing an earlier elution profile.

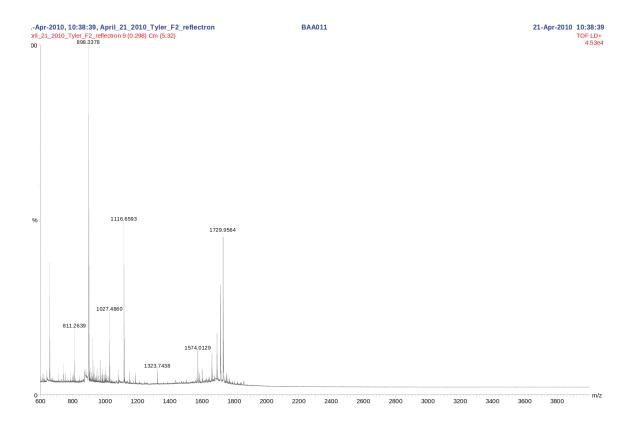

Figure 4.25: The TR-10-2 peptide construct was cleaved from the synthesis resin, lyophilized with excess water, and the crude was reconstituted with 50% ACN/ α -CHC matrix and the displayed reflectron-mode MALDI spectrum was collected. The target product should be ~1691 g/mol, and the large peak at ~1729 g/mol is almost certainly the K⁺ adduct. While this is a promising result for the first attempt at manual solid-phase peptide synthesis in our lab (and for a zoom-in version see Figure 4.26 on page 97), there are certainly some low molecular weight impurities.

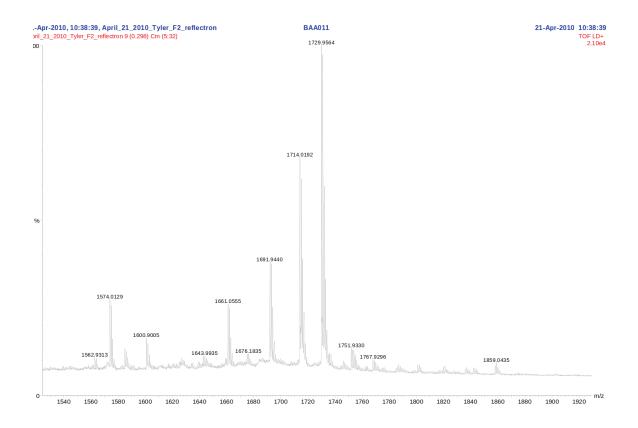

Figure 4.26: A zoom-in view of the reflectron-mode MALDI spectrum detailed in Figure 4.25 on page 96. The TR-10-2 target product is ~ 1691 m/z, while the Na⁺ and K⁺ adducts are also clearly visible ~ 1714 m/z and ~ 1729 m/z respectively.

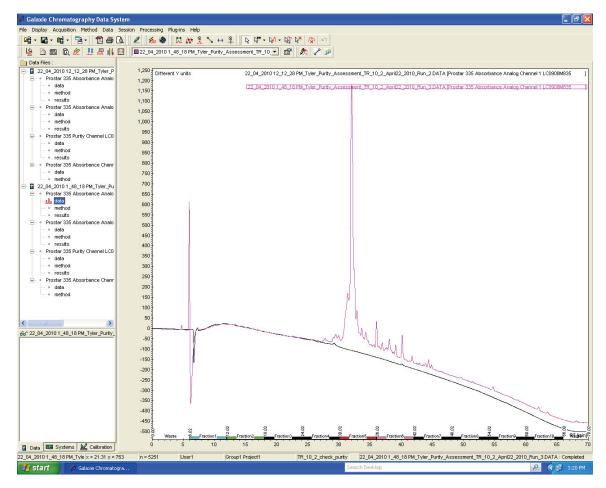

Figure 4.27: A crude preparation of TR-10-2 dissolved in ACN was loaded to a C18 analytical column via a 20 μ L sample loop (top injector) and subject to a 0.48 mL/min gradient: 1) 2-100% ACN in 60 minutes, 2) hold 100% ACN for 5 minutes, 3) ramp back 100-2% ACN in 1 minute. The trace shown here was monitored at 210 nm for the test run (pink) and a matching blank run with DI-H₂O (black) and fractions were collected in 6 minute windows between 6 and 66 minutes. The trace monitored at 280 nm is shown in Figure 4.28 on page 99.

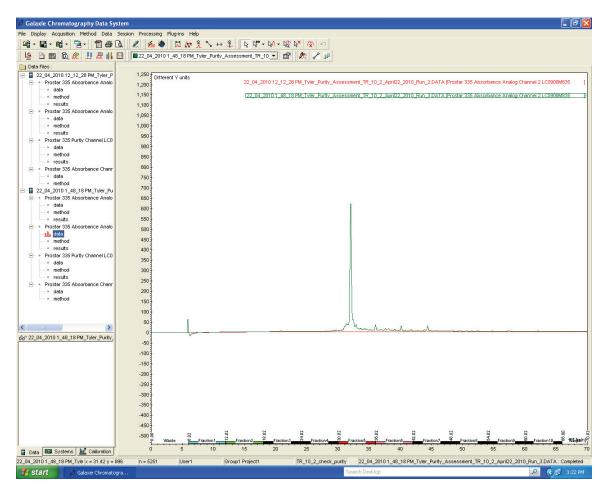

Figure 4.28: This is the TR-10-2 C18 analytical HPLC purity assessment run detailed in Figure 4.27 (page 98) monitored at 280 nm for the crude peptide (green) and the DI- H_2O blank (red).

$\mathrm{NH_{2}\text{-}MSGSHHHHHHGSSGENLYFQSLEYKEIDNTYLPKRPRPMLEKASIASGA}$ $\mathrm{MCALVFMLFVCLAFYLRFEQRAAKKDYKDDDDK\text{-}COO^{-}}$

Figure 4.29: Expected (82-residue) spitz fusion peptide produced by expression in pEXP5-NT/TOPO vector with TEV protease cleavage site highlighted in red. There is an N-terminal His tag and a C-terminal FLAG tag. The N-terminal Met is normally removed during production, shifting the expected average isotopic mass from \sim 9524 g/mol to \sim 9393 g/mol.

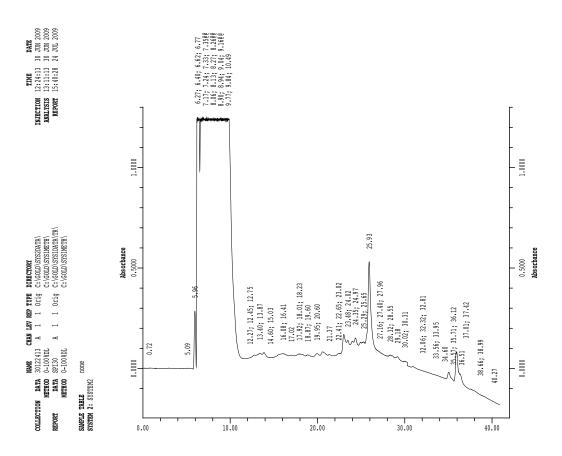

Figure 4.30: 250 μ L of ~1 mg/mL semi-crude (Ni-purified) expressed spitz construct in 50% H₂O/ACN was loaded to a C3 semi-preparative HPLC column and subject to a 2 mL/min gradient that ramps from 0-100% ACN at 2.5%/min. The trace shown here is monitored at 210 nm, and encouragingly the major peak ~26 minutes was confirmed by ESI-MS to correspond to a species with average molecular weight consistent with the target for the construct (not shown).

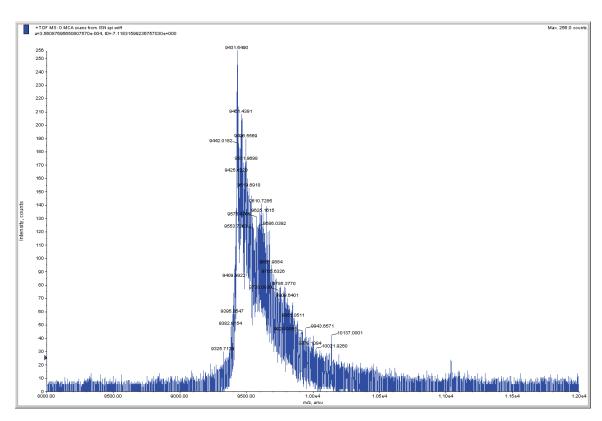

Figure 4.31: MALDI spectrum for the expressed spitz construct detailed in Figure 4.29 on page 99. The mass of the major peak is roughly consistent with a $\sim 50\%$ $^{15}{\rm N}$ incorporation. This is sensible as the bacteria were (accidentally) exposed to both isotopically enriched and unenriched nutrient sources.

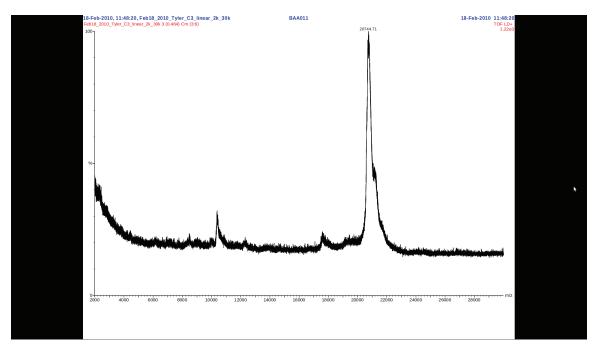

Figure 4.32: A crude expressed spitz construct dissolved in 50% $\rm H_2O/ACN$ (0.1% TFA) was treated with immobilized TCEP, separated from the reducing agent by centrifugation, diluted two-fold with sinapic acid (matrix solution), and the resulting linear-mode MALDI spectrum is shown here. After accounting for the linear-mode calibration, a potential dimer peak ~20.6 kDa dwarfs a peak consistent with the monomer ~10.3 kDa.

Table 4.1: Summary of MALDI-MS results for the HPLC fractions collected during the TR-09-1 crude peptide run described in Figure 4.12 on page 83. Samples were diluted two-fold in α -CHC matrix and the spectra were collected in reflectron mode.

Chapter 5

FGFR3 Simulation

5.1 Fibroblast Growth Factor Receptors

Fibroblast growth factor receptors (FGFRs) are a family of four FGF-activated receptor tyrosine kinase (RTK) transmembrane (TM) glycoproteins (155, 156, 157). All FGFRs have three extracellular immunoglobulin (Ig)-like domains, and alternative splicing of the proximal Ig-like domain in FGFRs 1-3 produces receptor isoforms with different ligand-binding specifities (158, 159, 160). The signaling complexity of the FGFR family is further compounded by the existence of at least 19 different FGFs (158, 161). Ligand-binding at the proximal Ig-like domain likely stabilizes the active dimer, with rearrangements in the TM and cytoplasmic tyrosine kinase domains driving autophorphorylation and signal transduction. FGFRs are of medical interest because many skeletal dysplasias and cancers are associated with mutations in FGFRs 1-3.

5.2 Achondroplasia: Specific Relevance Of FGFR3

Achondroplasia, the most common form of human dwarfism, was mapped to the short arm of chromosome 4 (162), and shortly thereafter a G380R mutation resulting from a transition or transversion in the FGFR3 gene was specifically identified as the major cause of the phenotype (163, 164). Indeed, G380R (in the FGFR3 TM

domain) is the underlying cause of achondroplasia in ~99% of cases (163, 164, 165). Achondroplasia is autosomal dominant with complete penetrance (166, 167), and in 80-90% of cases results from a spontaneous paternal germ line mutation (there is a correlation with increased paternal age) (168, 169, 170). While intelligence is normal in individuals with achondroplasia, there is increased mortality in the first four years of life and in the late fourth to fifth decades of life (171).

There is experimental evidence for increased signaling by the mutant FGFR3 with resultant negative regulation of bone growth (172). However, free energies of dimerization measured by fluorescence resonance energy transfer (FRET) in 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC) for wild-type and G380R TMD peptides match within the bounds of experimental uncertainty (173). Neutron diffraction and oriented circular dichroism spectroscopy indicate a 5 Å shift of the mutant peptide away from a POPC bilayer center (11). There appears to be a conceptual disconnect between the latter perturbation in FGFR3 mutant membrane topology relative to WT and the similar dimerization propensity to dimerize. Because of the medical relevance, there is a substantial motivation to gain insight into the influence of the G380R mutation on the dimerization properties of FGFR3.

In this chapter I describe and analyze coarse-grained molecular dynamics (CG-MD) simulations of the FGFR3 WT and G380R mutant TMDs in lipid bilayers. The analysis involves simulations for the WT homodimer, the heterodimer (because achondroplasia is autosomal dominant), and the mutant homodimer (section 5.4 on page 111). In section 5.5 (page 126) I focus specifically on the properties of the lipid bilayer proximal and distal to the peptide TMDs. Monomer simulations were also performed to control for the behaviour of the individual peptide constructs, and a preliminary analysis of these results is presented in section 5.6 (page 134).

5.3 Coarse-Grained Simulations And Glycophorin A Control

Ideal α -helical atomistic starting structures for FGFR3 constructs were built in PyMOL (174) based on the primary sequences of published experimental constructs (11) and the amino acids were coarse-grained as described previously for lipids (175). An approximate 4:1 mapping of heavy atoms (i.e., non-hydrogen atoms) to CG particles is performed to produce several specific particle types: polar (P), mixed polar/apolar (N), hydrophobic apolar (C), and charged (Q). A few additional particle subtypes allow fine tuning of Lennard-Jones potentials to reflect hydrogen-bonding propensities. Details of the amino acid to CG particle mapping process have been described elsewhere (176, 177). Lipid and water molecules were parametrized as described previously (175), and all simulations were performed using GROMACS (178). The MARTINI force field (179, 180) was employed for all simulations except for the FGFR3 monomer simulations (section 5.6.2 on page 135) which employ the Bond force field (176). Lennard-Jones interactions were shifted to zero between 9 and 12 Å, and electrostatics were shifted to zero between 0 and 12 Å. All simulations were performed at constant temperature, pressure, and number of particles. The temperature coupling of system components was performed independently for each component using the Berendsen algorithm at 323 K (181). The system pressure was semiisotropically coupled in the x, y, and z directions using the Berendsen algorithm. The time step for integration was 40 fs. VMD (182) was used for visualization and MDAnalysis (183) for parsing of trajectories. Parallel simulations and analyses were performed for glycophorin A (GpA) as described for previous CG-MD simulations (184). GpA is a well-characterized single-pass TMD protein which serves as a control for FGFR3—a protein for which there is no high-resolution structure available.

It should be noted that there are, of course, limitations to CG-MD simulations. The coarse-grained nature of the system provides improved performance at the cost of reduced accuracy and reduced similarity to the true biological system. Molecules diffuse at least four times faster than they would in a more realistic atomistic context, the involvement of water in many processes is often not well characterized because of the much larger size of CG-MD water particles, there are no hydrogen atoms or hydrogen bonds (only crude approximations and restraints), and the screening of electrostatic interactions is only approximated and frequently cut-off in a crude fashion.

5.4 Analysis Of FGFR3 And GpA *Dimer* Trajectories

5.4.1 Tracking The Distance Between Helices In A Trajectory

The initial separation between glycophorin A (GpA) and FGFR3 helices in the dimer simulations was ~55 Å, the same value used in previous GpA coarse-grained (CG) molecular dynamics (MD) simulations (184). Tracking the separation between helices in the POPC bilayer is useful for testing a number of properties. Perhaps most obvious is the assessment of the rate of dimer formation—if the separation between helices decreases and reaches the final dimer interhelix separation rapidly then dimer formation occurs quickly for a given construct. The stability of the dimer can also be assessed because increased interhelix separation after initial dimer formation may indicate that the dimer has dissociated, and frequent association and dissociation events may indicate a weak dimerization affinity. Performing many replicate simulations (see Table 5.1 on page 189) may also allow for the determination of whether the rates of dimerization and the dimer stability are consistent for a given dimer construct or vary stochastically between simulations.

My specific strategy was to track the closest interhelix approach using only C_{α} particles from each of the peptides. In each frame of a given simulation, a dis-

tance matrix for all possible interhelical C_{α} combinations was calculated with the minimum value defined as the closest approach distance. Although I coded a few MDAnalysis-dependent (183) python functions for these calculations, the most efficient function is closest_contacts_efficient() from the python module/library dimer_geometric_tools.py D.17 on page 356.

The closest interhelix approach is monitored during the first replicate trajectory of the GpA wild-type (WT) homodimer control condition in Figure 5.1 on page 138. Dimerization occurs very rapidly and the dimer is stable once formed. In contrast, dimerization takes $> 1\,\mu s$ in the FGFR3 WT replicate 3 simulation (Figure 5.2 on page 139), although the dimer is still stable once formed. The ninth FGFR3 heterodimer replicate simulation requires almost $4\,\mu s$ for dimerization (Figure 5.3 on page 139), but the dimer is again stable once formed. The second FGFR3 mutant homodimer replicate exhibits extremely fast dimerization and the dimer remains stable for the duration of the simulation (Figure 5.4 on page 140).

The outlined results may lead the reader to believe that the FGFR3 heterodimer forms more slowly than the WT or the mutant homodimer. However, it is important to consider the closest approach distance results across all of the replicate simulations (Figure 5.5 on page 141). It is clear from the latter plot that the variation in dimerization rates within any of the FGFR3 constructs is considerable. Thus, there appears to be a stochastic component to the rate of dimerization with no particular trend for FGFR3 WT, heterodimer or mutant homodimer conditions. However, in all cases, GpA and FGFR3 dimers are stable once formed in the self-assembled CG POPC bilayers used in these simulations since no dissociations were observed in 34 replicate simulations. The varied dimerization rates are consistent with the previously reported time required for WT GpA helix association in DPPC—varying from 0.5 to 3 μ s (with a 60 Å initial separation) (185). Note that the fifth GpA replicate simulation does not exhibit dimer dissocation—one of the helices adopted an orienta-

tion perpendicular to the membrane normal (and interacted with the other TM helix) before finally returning to a transmembrane orientation and forming a stable dimer.

5.4.2 Relative Helical Motion

All GpA and FGFR3 dimer constructs are stable once formed, but there is a stochastic component to the rate of dimerization. What are the helices doing during the variable simulation time prior to dimerization? One way to simplify the problem is to look at the motion of one helix in the fixed reference frame of the other. Specifically, in each frame of a (GpA or FGFR3) dimer simulation the coordinates of the geometric center of the first helix were subtracted so that its position was always at the origin. For consistency, the same subtraction per frame was applied to the coordinates of the geometric center of the second helix. Tracking the motion of the second helix in this fashion has been done previously for GpA dimer simulations in DPPC (184). The authors highlight one caveat—the dimerization interface will not be specific because the reference helix is free to rotate about its axis at the origin (as long as the geometric center is fixed).

The MDAnalysis-based relative_helical_motion() python function I wrote in the dimer_geometric_tools module D.17 (on page 356) performs the described adjustment of the trajectory reference frame and printing of new helix 2 coordinates. In the case of the first GpA control replicate, helix 2 follows a relatively straightforward path from its starting position to dimerization with helix 1 (Figure 5.6 on page 142). The case for FGFR3 wild-type replicate 7 is more convoluted, with helix 2 moving through several periodic boundaries before dimerizing with a mirror image of the reference helix (Figure 5.7 on page 142). The ninth heterodimer FGFR3 replicate requires nearly $4 \mu s$ for dimerization (Figure 5.3 on page 139) and accordingly helix 2 moves through a large distance, including many periodic boundaries, before dimerization with a mirror image of helix 1 (Figure 5.8 on page 143). The rapid dimerization of the second FGFR3 mutant homodimer replicate (Figure 5.4 on page 140) is con-

sistent with the straightforward path followed by helix 2 for dimerization with helix 1 in this simulation (Figure 5.9 on page 143). Thus, the variety of dimerization rates is reflected in the relative 'wandering' motions of the helices.

5.4.3 Helix Crossing Angle

Sections 5.4.1 (page 111) and 5.4.2 (page 113) demonstrate a wide variety of helix dimerization rates and wandering distances before dimerization, but a stable dimer once it has formed. The observations are consistent with an unbiased simulation setup. Had the helices been placed too close together at the start of the simulation, the dimerization rates would likely have been more consistent with no opportunity for relative wandering motion. Given the formation of stable and unbiased dimers we now focus on the details of the dimer proper.

It has been well established that GpA dimers exhibit a strong preference for righthanded helix crossing angles from experimental high-resolution structures (186, 187) and computational studies in DPPC (184). The first GpA replicate simulation in POPC is consistent with this behaviour (Figure 5.10 on page 144). There is currently no high-resolution experimental structure of the FGFR3 TM domain (we employ an ideal α -helix), so it is important to establish that the dimer configuration for the GpA control is consistent with previous experimental and computational findings. Unlike GpA, the first FGFR3 WT homodimer replicate exhibits dimerization with a bimodal helix crossing angle distribution, and perhaps a slight preference for a left-handed crossing angle (Figure 5.11 on page 145). The ninth replicate FGFR3 heterodimer simulation appears to exhibit a preference for a right-handed helix crossing angle (Figure 5.12 on page 146), but there is a small number of sampled dimer frames because this trajectory required so long for dimerization (Figure 5.3 on page 139). The first replicate of the FGFR3 mutant homodimer construct exhibits a bimodal helix crossing angle distribution (Figure 5.13 on page 147) similar to that observed for the wild-type replicate above.

While there is value in analyzing replicate simulations on an individual basis, it should also be clear that it is important to perform many replicates and study the merged results to establish overall trends. In particular, the helix crossing angle results merged over all the replicate trajectories indicate that all FGFR3 constructs (including heterodimer) exhibit bimodal helix crossing angle distributions, in contrast to GpA which exhibits an overall preference for a right-handed helix crossing angle (Figure 5.14 on page 148). The bimodal helix crossing angle distribution for FGFR3 constructs might be explained by alternation between configurations as the helices oscillate closer and farther apart in the dimer. However, helix crossing angles were independent of the closest interhelical approach between C_{α} particles for all FGFR3 constructs (Figure 5.15 on page 149).

5.4.4 Correlated Helical Motion

There is stochastic wandering prior to dimerization in the GpA and FGFR3 replicate trajectories, and the dimers are stable once formed, but the helix crossing angle distribution for all FGFR3 constructs is curiously bimodal. It is not clear how the FGFR3 helices move relative to one another in the context of the dimer since both left- and right-handed crossing angles are sampled in a given trajectory. However, since the dimers are stable we would still expect them to move together in the POPC bilayer. To test for coordinated helical motion, I first tracked the Z coordinate (along the bilayer normal) of the geometric center of the C_{α} particles of each helix relative to the center of the bilayer. The center of the bilayer was defined as the average of the center of mass coordinates of the two leaflet phosphate CG particle populations, and the MDAnalysis-dependent python function I wrote for this calculation (geo_Z_tracking_relative_to_bilayer()) is stored in the python library dimer_geometric_tools.py D.17 on page 356. An example of the results of this analysis for the first GpA replicate simulation are shown in Figure 5.16 on page 150. While there is certainly evidence for coordinated excursions of the helical geometric

centers away from the center of the bilayer, it is rather cumbersome to quantify the degree of coordinated motion by inspection.

To quantify the degree of coordinated helical motion in GpA and FGFR3 dimer simulations, I calculated the absolute correlation coefficient (|R|) between the Z coordinates of the geometric centers of the helices before and after dimerization. The python split_Z_file() function in the dimer_geometric_tools.py library (D.17 on page 356) splits the helix geometric center Z coordinates into pre- and post-dimerization files and produces the corresponding linear correlation coefficients. The results for individual replicates are summarized in Figure 5.17 on page 151, and for merged data that includes all replicates per condition in Figure 5.18 on page 152. For all constructs, as expected, helical motion is more strongly correlated following dimerization. The larger correlations observed for GpA dimers relative to FGFR3 constructs is consistent with previous results indicating that GpA forms much stronger dimers than FGFR3 (188).

5.4.5 Identification Of Predominant Interhelical Contacts

The unbiased GpA and FGFR3 simulations exhibit formation of stable dimers which move together in the membrane. In addition, FGFR3 has no apparent preference for left- or right-handed helix crossing angles. However, these are fairly broad properties, and I would now like to focus on more specific aspects of the dimer configuration. Which residues feature most prominently at the dimer interface for FGFR3? Without a high-resolution structure of the FGFR3 TM domain available, the identification of important dimer interface residues via simulation may provide insight into the molecular mechanism of pathology in achondroplasia and other skeletal dysplasias.

I devised a simple method to parse a CG-MD trajectory for the predominant interhelical dimer contacts. For each frame of a simulation (if the helices are within 7 Å), a distance matrix of all possible interhelical C_{α} - C_{α} combinations is calculated. The five smallest distances for each frame are recorded along with the corresponding residue identifiers. The probability for each residue to appear in the five closest dimer contacts is then calculated based on the total number of these contacts in which the residue is found divided by the total number of contacts (which is 5× the number of dimer frames in the simulation). Separate close contact probabilities are calculated for matching residues in each helix in order to assess symmetry. I have written MDAnalysis-dependent python functions to calculate the residue close contact probabilities for each helix in: a single GpA trajectory (top_five_closest_residues_GpA()), a single FGFR3 trajectory (top_five_closest_residues_FGFR3), and aggregate results for each of the FGFR3 constructs across all replicate trajectories (merged_top_five_FGFR3()). The functions are all stored in the library module D.17 (dimer_geometric_tools.py) on page 356. In the case of aggregate probabilities, the head script (analyze_FGFR3_dimer_simulations.py) D.15 on page 338 must also call a second library function (parse_overall_FGFR3_top_five_data()) to parse the larger set of data.

The results of the residue close contact probability analysis for the first replicate GpA simulation are plotted in Figure 5.19 on page 152. The predominant residues are representative of the other GpA replicates with G79, G83, and T87 among the most likely residues in the closest interhelical contacts. Other candidates (L75, I91) are spaced at 4 residue intervals, which is consistent with the identification of a helical face. G79, G83, and T87 have previously been identified as experimentally crucial interfacial contacts (189). The analysis procedure I have employed therefore produces computational predictions of dimer interface residues that are consistent with experiment for GpA, and this provides confidence for the application of this method to the FGFR3 TM domain.

Three residues stand out from the equivalent aggregate analysis over all trajectories for each of the three FGFR3 conditions—G370, A374, R397 (Figure 5.20 on

page 153). Other prominent close contact residues are spaced at 3-4 residue intervals, which is consistent with the identification of a specific helical face of FGFR3. It is noteworthy that G380/R380 (the site of the achondroplasia mutation) does not feature prominently as a close contact residue, nor does A391 (mutation to E results in Crouzon syndrome) (190). Does it make sense that residues mutated in disease are not located directly at the dimer interface? Strikingly, G370 (one of the most prominent contacts) is mutated to C in type 1 thanatophoric dysplasia, which has a more severe phenotype than achondroplasia and is normally neonatal lethal (191). It is possible that the severity of the phenotype correlates with the proximity of the mutated residue to the dimer interface. Furthermore, G370 was recently localized to the FGFR3 dimer interface by site-specific infrared dichroism (192). The propensity for disulfide formation in FGFR3 follows the trend Cys370 > Cys371 > Cys375 (193), which is also consistent with an interfacial position for residue 370. R397, another of the prominent interfacial contacts, is part of the C-terminal CRLR tetrapeptide, which can be removed to increase the dimerization affinity of FGFR3 to match that of GpA (192).

5.4.6 Identification Of Dimer Interfaces

The experimental and clinical support for the proposed FGFR3 dimer interface residues is encouraging. Despite identification of a small set of candidate interfacial residues in the FGFR3 dimers, it is not clear if the broad distribution of allowable helix crossing angles (section 5.4.3 on page 114) results from sampling of different dimer interfaces. To test the possibility that more than one dimer interface can be sampled in the FGFR3 dimer, I employed a simplified reference frame. For all three FGFR3 conditions, a reference structure corresponding to the first helix in the first frame of the first WT FGFR3 simulation was used. The first helix in all frames of all FGFR3 replicate simulations was rmsd-fixed to match the configuration of that reference structure. Applying the same coordinate transformation to the second helix

allows for the assessment of the relative position of helix 2 while helix 1 is fixed in a single configuration. The geometric center of helix 2 was tracked in this adjusted coordinate system to test for the presence of multiple dimer interfaces. This is similar to a strategy previously employed to study the GpA dimer interface (184). I have written python MDAnalysis-dependent functions for calculating the positional probability of helix 2 in the rmsd-fixed reference frame of helix 1 for individual GpA and FGFR3 trajectories (fixed_helix_thermal()) and for results merged across all replicates for a given FGFR3 condition (fixed_helix_thermal_merged()). While the former function contains its own data-binning routine for outputting the helix 2 positional probabilities, the latter function is called prior to a separate binning routine (thermal_bins()). All three functions are stored in the python library dimer_geometric_tools.py D.17 on page 356, and controlled from the head script analyze_FGFR3_dimer_simulations.py D.15 on page 338.

The result for the first control replicate GpA trajectory (representative of the other GpA replicates) is shown in Figure 5.21 on page 154. The positional probability of helix 2 is consistent with a primary dimer interface at the 'bottom right' of helix 1 and a secondary interface at the 'top right.' Since ten replicate simulations were performed for each of the FGFR3 dimer conditions (Table 5.1 on page 189), the aggregate helix 2 positional probability results across all replicates were calculated for each condition (Figure 5.22 on page 155). All three FGFR3 constructs have a primary dimer interface at the 'bottom left' of helix 1. While the WT has no major dimer interaction at the 'bottom right' of helix 1, there is a progressively greater likelihood of helix 2 interacting with helix 1 at the 'bottom right' when looking at the WT \rightarrow heterodimer \rightarrow mutant homodimer results. Thus, a secondary dimer interface progressively appears in the FGFR3 heterodimer and mutant homodimer simulation conditions.

5.4.7 Dimer Interface Transitions

There is evidence for primary and secondary dimer interfaces for FGFR3 (and GpA) dimers (section 5.4.6 on page 118). It is not immediately clear how the helices transition between the interfaces. One possibility is a continuous sampling of the two interfaces with a bias toward the primary interface. However, a less frequent interface transition scheme is also possible—there may be discrete periods of the simulation at each of the interfaces with a single or a few transition points. To distinguish between these transition schemes I employed a simplified reference frame with rmsd-fixing of helix 1, as outlined in section 5.4.6 (page 118). However, instead of calculating the positional probability of helix 2, I simply tracked its geometric center during the trajectory by using a third plotting dimension—the frame (simulation time). The MDAnalysis-dependent python function frame_abstracted_relative_position() in the dimer_geometric_tools.py module D.17 (page 356) was used to parse individual GpA and FGFR3 trajectories in the described fashion.

An example of the result of this analysis on a representative GpA simulation trajectory is shown in Figure 5.23 on page 156. The stable helix 2 position at the 'bottom right' of helix 1 is apparent, with only one substantial excursion to the secondary dimer interface late in the simulation. The excursion is clearly discrete—there is a single point of exit from the primary interface and a single point of return to the primary interface. The other GpA replicates exhibit similar discrete (rather than continuous sampling) transitions between the primary and secondary dimer interfaces.

The FGFR3 mutant homodimer replicate 4 simulation is an interesting target for this analysis because there is a roughly equivalent positional probability for helix 2 at the primary and secondary dimer interfaces (Figure 5.24 on page 157). Tracking the geometric center of helix 2, it is apparent that helix 2 starts the simulation at the secondary interface ('bottom right' of helix 1), and exhibits a very large amplitude of motion at this interface (Figure 5.25 on page 158). However, roughly half way

through the trajectory there is a transition to the primary interface ('bottom left' of helix 1) where the position of helix 2 is much more stable. This is a representative result of discrete interface transitions in the mutant homodimer FGFR3 condition.

5.4.8 Identification Of Representative Dimer Interface Structures And Contacts

The FGFR3 mutant homodimer (and to some extent the heterodimer) has both primary and secondary dimer interfaces which are occupied for discrete periods of the simulations (section 5.4.7 on page 120). It would be informative to pull out a representative structure for each of the interfaces or to determine which interfacial residue contacts predominate each of the configurations. In principle, it should be possible to extract structures from simulation frames chosen manually from the plots in section 5.4.7. However, the 3D perspective view of these plots (*i.e.*, Figure 5.25 on page 158) makes it cumbersome to extract appropriate frames to represent a particular interface.

One way to simplify the plots is to remove one of the dimensions. It is crucial to track the simulation time or frame number because we need to know the exact frame that corresponds to a coordinate (interface position) for helix 2 in the reference frame of rmsd-fixed helix 1. However, instead of tracking both x and y coordinate positions it is possible to convert the Cartesian coordinates to a single polar angle θ (in the two-dimensional polar coordinate system).

An example plot of θ and Ω (helix crossing angle) tracked as a function of simulation frame number is shown in Figure 5.26 on page 159 for the first replicate GpA simulation. The excursions of helix 2 to the secondary dimer interface are discrete but brief for GpA, and there is apparently no substantial change in Ω for GpA dimer interface transitions. This is not surprising given the strong preference of GpA dimers for right-handed helix crossing angles (section 5.4.3 on page 114). In contrast, there appears to be a change in Ω as the FGFR3 dimer transitions from the secondary

to the primary interface in the fourth replicate mutant homodimer simulation (Figure 5.27 on page 160). Initially, at the secondary interface, Ω is primarily negative (right-handed) and then transitions to a bimodal distribution about 0 as the dimer assumes the primary configuration. It is also notable that there is a much larger amplitude of motion for FGFR3 helix 2 at the secondary interface when compared with its relatively stable position at the primary interface, consistent with observations in section 5.4.7 (page 120).

The demonstrated procedure for selection of representative dimer interface structures (simulation frames) from the helix 2 polar angle in the rmsd-fixed frame of helix 1 is 'manual,' and may not be the ideal way to address the selection of a representative structure across the population of all simulation replicate frames. To address the quality of the manually selected representative frames I have highlighted them in the context of a direct correlation between helix 2 polar θ and Ω for all frames in a given FGFR3 simulation (Figure 5.28 on page 160). The calculations were performed using the correlate_helixcrossing_polar_theta() function in the dimer_geometric_tools.py module D.17 (page 356). Even in the simple case of the FGFR3 WT there is an obvious complication with the manual selection procedure the selection of a single representative structure will always, by chance, pull out a leftor right-handed helix crossing configuration even though both are possible at the WT (primary) interface. The same problem crops up for selection of the representative primary interface in the FGFR3 heterodimer and mutant homodimer, and is potentiated by the comparison with the secondary interface in these conditions. Thus, while it is apparent that the FGFR3 secondary dimer interface represents mostly righthanded helix crossing configurations, the bimodal helix crossing angle distribution at the primary interface means that comparison of the representative primary and secondary interfaces would depend on the stochastic selection of a left- or right-handed dimer from the primary interface.

With the above limitations in mind, the FGFR3 dimer structures corresponding to the representative frames highlighted in Figure 5.28 (page 160) are shown in Figure 5.29 on page 161. By inspection, the FGFR3 secondary dimer interfaces are similar when compared between heterodimer and mutant constructs while there appear to be more substantial differences between representative primary interface structures. This is consistent with the wider variety of helix crossing angles at the primary interface and the stochastic component to manual structure selection described above.

The closest contacts by residue for each helix in the representative constructs were calculated using the closest_approach_representative() function in the dimer_geometric_tools.py module (D.17 on page 356). Plots of the reciprocal (for visualization purposes) closest contact distances for each residue in the constructs are shown in Figure 5.30 on page 162. The WT 'secondary' interface refers to a 'top left' position for helix 2 in Figure 5.22 on page 155, and is distinct from the secondary dimer interface which develops in the heterodimer and mutant. Nonetheless, there are some noticeable differences in the WT contacts between the two interfaces and R397 in particular has a much closer contact in the primary interface. The heterodimer interfaces differ strikingly at the N-terminus (including G370 and A374) while R397 and other C-terminal residue contacts are more similar. Less striking differences are observed between the interface contacts for the mutant homodimer, consistent with selection of representative constructs that have the same helix crossing angle (compare heterodimer and mutant selections in Figure 5.28 on page 160).

5.4.9 Population-Based Dimer Interface Classification

The previous section (5.4.8 on page 121) highlights the limitations with selection of single representative dimer interface structures for FGFR3. The next step is to use a clustering or population-based approach to classify groups of frames falling into representative categories to avoid the stochastic problems with selection of single

representative frames. GROMACS tools has a built-in clustering utility, g_cluster, which served as the starting point for this analysis. I used the g_cluster single linkage and gromos methods for generating the major clusters in each of the replicate simulations. Single linkage will add a frame to a cluster as long as it is within a specified rmsd-cutoff of any frame within that cluster, while the gromos algorithm is more sophisticated, using a neighbour clustering cut-off technique as described in (194). Plots correlating the % of trajectory structures in the major cluster with the rmsd of the major cluster are shown for the single linkage (Figure 5.31 on page 163) and gromos (Figure 5.32 on page 164) algorithms, as well as a direct comparison of the two (Figure 5.33 on page 165), using a 0.4 nm rmsd cutoff. The gromos algorithm is clearly more stringent—producing major clusters with lower rmsd values and therefore lower % frame incorporation into the major cluster. It is also notable that GpA trajectories consistently have less variation (lower rmsd), despite a similar or higher % incorporation, within their major clusters compared with FGFR3. This is consistent with the formation of a stronger dimer by GpA (188).

While the above GROMACS-based clustering methods produce sensible differences between GpA and FGFR3 trajectories, it would be preferable to incorporate the polar angle (θ of helix 2 in the reference frame of rmsd-fixed helix 1) into the population-based clustering method because θ (a change in position of helix 2) is the basis of the dimer interface classification. The basic idea is to select a population of frames within a certain set of θ bounds rather than a single frame within the interface boundary and then analyze the members of each interface population as a whole. One of the challenges for automated classification of simulation frames within populations of interfaces are the large-amplitude and short-lived excursions of FGFR3 away from the secondary interface and occasionally the primary interface. I do not want every brief excursion back and forth between primary and secondary interfaces to be treated as a stable transition from one interface to the other. Instead, I smoothed

the data for each FGFR3 replicate trajectory using a weighted moving average and a 'spike-filter.' Specifically, the simple_moving_average_polar_theta() function in the dimer_geometric_tools.py module D.17 (page 356) performs a few analysis steps: 1) For each replicate simulation, select only frames θ values that correspond to dimer configurations (frames after helix-helix closest $C_{\alpha} < 6$ Å). 2) Subject each data point to a 'spike filter:' if the current θ differs by more than 1.0 radians from the average θ values of both the 20 preceding and 20 following frames, its instantaneous θ is replaced by the average of the previous 10 data points. It is important to check both preceding and following θ trends because if θ only deviates substantially on one side of the current data point, this may reflect a stable transition between interfaces that is not an intended target for attenuation of a sudden change in θ . Note that using a large window for the weighted average instead of this kind of spike filter is also not desirable because it will produce a 'lag' in the data with the large window tail. 3) Use the standard python numpy.convolve() function to calculate a linear weighted moving average with a window size of 10 on the current spike-filtered data set. The simplification of the automated classification of frames to representative dimer interfaces as a result of the smoothed θ values is apparent with the attenuated fluctuations in the new data, as highlighted in Figure 5.34 on page 165.

Finally, the resulting data is parsed for the predominant interfacial residue contacts (as described in section 5.4.5 on page 116) at each of the interfaces, which are defined based on classification of the 'smoothed' polar θ values:

Primary interface (rad): $-3.0 < \theta < -1.5$

Secondary interface (rad): $-1.0 < \theta < 1.0$

Other interfaces (rad): remaining θ

The specific filtering and analysis implementation is available in the interface-

top_five_data() functions in the dimer_geometric_tools.py module D.17 (page 356). The predominant contacts, across all 30 FGFR3 dimer simulations (WT, heterodimer and mutant), for each of the FGFR3 dimer interfaces are shown in Figure 5.35 on page 166. There is a striking loss of contact symmetry at G370 (and to some extent R397) at the secondary interface compared with the primary interface. The other interface(s) exhibit a broad contact profile, which may simply reflect the fact that more than one discrete alternative interface exists outside the primary and secondary. Since G370 and R397 are candidates as important dimer contacts (section 5.4.5 on page 116), the present evidence is consistent with changes at critical dimer interface residues between primary and secondary interfaces and the existence of distinct configurations at each interface.

5.5 Analysis Of Lipid Bilayer In GpA And FGFR3 Simulations

The previous section (5.4 on page 111) concerns the analysis of the peptide components of the GpA and FGFR3 dimer trajectories. However, the peptides are not simulated in a vacuum and I will now focus on the analysis of the POPC lipid bilayer surrounding the TM segments in these simulations. One of the challenges with lipid bilayer analysis is the categorization of individual phospholipids to a particular leaflet. MDAnalysis propagates a network of connections between selected particles (*i.e.*, phosphates in lipid headgroups) using a cut-off distance which determines the leaflet groupings. This may cause problems if any lipid in one leaflet approaches a lipid in the other by the cut-off distance because the network of connections could then propagate through both leaflets and their separate definitions would be lost (Figure 5.36 on page 167). To simplify the tracking of lipid leaflets, I defined the leaflets in the first frame of each simulation and assigned each phosphate particle permanently

to a specific leaflet. In this manner, if a phospholipid moves closer to the center of the bilayer it will not abrogate the leaflet definitions because each phosphate is assigned permanently to one leaflet from the first frame (there is no propagation step in each frame).

5.5.1 Testing For Phospholipid 'Flip-Flop'

The method for leaflet selection outlined above handles bilayer pinching/narrowing more gracefully than a network propagation procedure in each frame. However, my method could produce misleading results if a phospholipid 'flip-flops' between leaflets and is treated as a member of the incorrect leaflet in a calculation. To test for lipid 'flip-flop' I wrote the flip_flop_tracker() function in the dimer_geometric_tools.py module (D.17 on page 356), which performs the following steps: 1) Selection of phosphate particles and their assignment to a particular leaflet, in the first frame of the simulation, by network propagation using the MDAnalysis built-in LeafletFinder function. The latter uses a networking cut-off optimized by the built-in optimize_cut-off function, which is called by the optimize_leaflet_selection_cutoff function in the dimer_geometric_tools.py module (D.17 on page 356) 2) With the absolute leaflet assignments complete, iterate through each frame of the simulation and track the largest and smallest Z (along bilayer normal) coordinates for each set of leaflet phosphates. 3) Calculate the average Z coordinate of all phosphates in the system for each frame to provide an estimate of the center of the bilayer.

This way, any replicate simulation can be tracked for phosphates which cross the center of the bilayer and enter the other leaflet, and I will simply discard those replicates with flip-flop activity from any leaflet-based analyses. One of the five GpA replicate simulations was discarded from bilayer analysis because of the inplane orientation assumed by one of the peptides during this simulation, while the other four did not show evidence of lipid flip-flop. A representative example from the fourth GpA replicate simulation is shown in Figure 5.37 on page 167. Interestingly, $\frac{2}{10}$

replicates in the FGFR3 WT condition exhibited lipid flip-flop between leaflets despite the same bilayer lipid (POPC). An example of a phosphate headgroup crossing the bilayer leaflet boundary, in the first replicate FGFR3 WT simulation, is shown in Figure 5.38 on page 168. None of the ten FGFR3 heterodimer replicates exhibited lipid flip-flop activity (*i.e.*, Figure 5.39 on page 169), nor did any of the ten FGFR3 mutant homodimer replicates (*i.e.*, Figure 5.40 on page 170).

The number of replicate simulations discarded because of lipid flip-flop is low, and the absolute assignment of lipid phosphates to a particular leaflet in the first frame of each simulation is therefore a robust method which can serve as the basis for subsequent bilayer parameter measurements.

5.5.2 Protein-Local And -Distal Bilayer Thickness

The previous section (5.5.1 on page 127) dealt with the limitations of my lipid bilayer leaflet selection procedure. With a robust method for leaflet selection established, the focus now switches to determination of the bilayer thickness near (local to) the TM monomers or dimers in comparison to the distal bilayer thickness (away from the TM segments). I have written the MDAnalysis-dependent python function analyze_leaflets() in the dimer_geometric_tools.py module D.17 (page 356) to perform a number of analysis steps on each of the replicate trajectories: 1) Assign top and bottom leaflet phosphate populations in the first frame as described above. 2) Select all phosphate particles in the top and bottom leaflets within a 16 Å shell of either TM segment. Also, select all phosphate particles in the top and bottom leaflets that are more than 16 Å away from both TM segments. 3) Calculate the difference between the Z coordinates of the centers of geometry for the respective phosphate particle populations selected in the previous step. These are estimates of bilayer thickness in protein-local and protein-distal regions of the system.

The interphosphate bilayer thickness tracked in protein-local and protein-distal regions is shown in a representative plot from the fourth GpA replicate results (Figure 5.41 on page 171). By inspection, there is at least a 4 Å thinning of the bilayer in protein-local versus -distal regions. While some protein-local bilayer thinning is also observed in the case of the FGFR3 WT, it is not nearly as substantial (*i.e.*, Figure 5.42 on page 172). Similar results were observed for the FGFR3 heterodimer replicates (*i.e.*, Figure 5.43 on page 173). One of the FGFR3 mutant homodimer replicates exhibited a dip in protein-local bilayer thickness roughly half way through the simulation (Figure 5.44 on page 173), but this was not observed for the majority of the mutant replicates.

The substantial POPC bilayer thinning observed near GpA may relate to hydrophobic mismatch with this 23 residue TM construct, while the moderate bilayer thinning in proximity to each of the FGFR3 constructs may be explained by the longer TM segments (33 residues). However, there is an additional concern with the bilayer thickness analysis presented in this section—are the 16 Å protein-local shells including a sufficient number of lipid phosphates? For example, if typically only two lipids are within the defined local shell of each peptide, there is an undesirably small sample size for the measurement. This is addressed in the next section.

5.5.3 Protein-Local And -Distal Lipid Shell Counts

The previous section (5.5.2 on page 128) includes analysis consistent with protein-local bilayer thinning in GpA and (to a lesser extent) in FGFR3 simulations. However, it is important to determine whether a sufficient number of protein-local lipid phosphates were captured in the defined 16 Å shells around the C_{α} particles of each TM segment. The count_lipids_in_local_shell() function in the dimer_geometric_tools.py module D.17 (page 356) was designed to count the number of phosphates in the top and bottom leaflets within 16 Å of either peptide in the dimer simulations as well as the total top and bottom leaflet phosphate counts for positions farther than 16 Å from either TM segment. Representative results for GpA are shown in Figure 5.45 on page 174. As expected, there are considerably more protein-distal than protein-

local lipids in each leaflet. It is noteworthy that the peptide dimerization event is clearly observable as a synchronized increase in the number of protein-distal lipids, and this is sensible because the protein-local shells overlap following dimerization. There are more lipids in the distal bottom leaflet relative to the distal top leaflet, but the reason for this is not clear and may simply relate to a partially random distribution of lipids during the POPC bilayer self-assembly process. A closer look at the peptide-local lipid shell counts reveals roughly 10 lipids per leaflet near a given GpA monomer (Figure 5.46 on page 174).

The FGFR3 WT also has a larger lipid population in the distal bottom leaflet versus the top (*i.e.*, Figure 5.47 on page 175). Again, there is a clear indicator of peptide dimerization as the distal leaflet lipid counts increase in unison, and the local lipid shell counts appear to synchronize at this time. The local shell count synchronization is especially apparent in the closer view (Figure 5.48 on page 175), which also reveals that 10-15 lipids are included per leaflet within 16 Å of a given FGFR3 monomer. In the pre-dimer state, one of the monomers fluctuates to some lower lipid shell counts.

The gap in distal leaflet lipid populations is much smaller in the FGFR3 heterodimer replicates (*i.e.*, Figure 5.49 on page 176), which is consistent with a stochastic component to leaflet population distribution during the bilayer self-assembly process. The ninth heterodimer replicate simulation tracked in Figure 5.49 again exhibits a synchronized increase in distal leaflet lipid populations coinciding with peptide dimerization (the extended time required for dimerization of this replicate is consistent with observations in section 5.4.1 on page 111). The local lipid shell counts also synchronize upon dimerization (Figure 5.50 on page 176), and 10-15 lipids are included per leaflet within 16 Å of a given FGFR3 monomer. Again, in the pre-dimer state, one of the monomers fluctuates to some lower lipid shell counts.

The behaviour of the FGFR3 mutant homodimer is very similar to the heterodimer

(i.e., Figure 5.51 on page 177 and Figure 5.52 on page 177). Overall, the 10-15 lipids per leaflet counted in the protein-local shells for GpA and FGFR3 replicates provide confidence that the 16 Å local shell definition is appropriate. A larger number of lipids (~ 90) was reported in a defined local shell around another simulated protein in the literature (195), but the rhomboid protease in question is substantially larger than the dimers reported here. With verification of the local lipid shell definition complete, the next section returns to the issue of tracking bilayer thickness, with an emphasis on the effect of dimerization on local bilayer thickness.

5.5.4 Overall Bilayer Thickness Analysis For GpA And FGFR3 Simulations

With added confidence in the protein-local and -distal lipid selection methodology (section 5.5.3 on page 129), and evidence for protein-local bilayer thinning in the CG simulations for GpA and FGFR3 (section 5.5.2 on page 128), it is desirable to analyze the data gathered across all replicate simulations for average bilayer thickness values before and after peptide dimerization. The function bilayer_thickness_average_results() in the dimer_geometric_tools.py module D.17 (page 356) performs a few tasks in this analysis: 1) Using the previously calculated closest interhelical C_{α} approach (per frame) during each of the trajectories (section 5.4.1 on page 111), determine the frame number at which dimerization occurs (defined as $d_{C_{\alpha}-C_{\alpha}} < 6$ Å). 2) Parse the previously calculated protein-local and -distal bilayer thickness results (section 5.5.2 on page 128) and split the protein-local data in to pre- and post-dimerization lists, combining results from each monomer. The protein-distal bilayer thickness values are not split on the dimerization frame. In total, this produces three separate lists for each of the GpA, FGFR3 WT, FGFR3 heterodimer, and FGFR3 mutant homodimer conditions.

Finally, the bilayer_stats() function in the same module is called separately by the head script (analyze_FGFR3_dimer_simulations.py on page 338) to deter-

mine the average and standard deviation values for the global lists produced by bilayer_thickness_average_results(). The overall results for GpA and the FGFR3 conditions are summarized in Figure 5.53 on page 178. While it is clear that GpA and FGFR3 TM peptides cause local bilayer thinning, it is not clear within one standard deviation that any substantial local bilayer thinning occurs following dimerization. The latter observation may be consistent with a stable dimerization process because additional local bilayer thinning following dimerization may come with an entropic lipid rearrangement penalty.

5.5.5 DPPC: The Effect Of Phospholipid Type On FGFR3 Dimer Behaviour

In addition to the manually setup and executed dimer simulations summarized in Table 5.1 (page 189), I also submitted FGFR3 WT, heterodimer and mutant homodimer configurations to the high-throughput GROMACS-based SIDEKICK automated simulation program (196). SIDEKICK performs the setup and execution of a large number of coarse-grained replicate simulations while abstracting the details from the user, and performed a total of 98 FGFR3 WT replicates, 96 FGFR3 heterodimer replicates, and 92 FGFR3 mutant homodimer replicates, with each replicate consisting of a 0.5 μ s trajectory. One limitation of this high-throughput framework is that only DPPC may be used as the bilayer lipid (because it has been sufficiently well characterized for coarse-grained membrane-based simulations to be used in an automated context). I've used POPC for the manually executed simulations for consistency with experimental FGFR3 studies (11, 173). However, I have performed a preliminary analysis on the SIDEKICK results to probe the effect of DPPC versus POPC on FGFR3 dimer behaviour.

5.5.5.1 FGFR3 Dimer Stability In DPPC

All of the GpA and FGFR3 constructs I have analyzed from CG simulations in POPC bilayers have formed stable dimers which do not dissociate once formed (see section 5.4.1 on page 111). However, WT and mutant GpA TM constructs have been observed to dissociate in DPPC-based CG simulations (184). In contrast, more recent DPPC-based CG simulations of WT and mutant GpA TM peptides do not exhibit any dissociation behaviour (185), and the authors suggest the discrepency with previous work is related to the more thoroughly calibrated MARTINI force field they employ.

FGFR3 WT, heterodimer, and mutant homodimer constructs all exhibited dissociation behaviour in DPPC bilayer-based SIDEKICK CG simulations (Figure 5.54 on page 179). The large number of replicate simulations were parsed by the closest_cont-acts_efficient_SIDEKICK() function in the dimer_geometric_tools.py module (page 356), which was controlled from a head script designed for the high-throughput data organization (analyze_sidekick_FGFR3_dimer_simulations.py). The reduced dimerization propensity is probably not the expected consequence of switching to a more saturated phospholipid, but given the variety of reported results within DPPC alone, it is not surprising that different phospholipids encourage varied dimerization behaviour.

5.5.5.2 FGFR3 Dimerization Interface In DPPC

In section 5.4.6 (page 118) I described a method for assessing the number of dimer interfaces explored by helix 2 when helix 1 is rmsd-fixed to a reference frame. For FGFR3, this reference frame is the configuration of helix 1 in the first frame of the first WT replicate simulation. Using the same (POPC-based) reference configuration for DPPC simulations, I have once again tracked the positional probability of helix 2, in this case to provide a direct comparison of the DPPC and POPC dimer interfaces for the three FGFR3 conditions. It is especially useful that the sample sizes are comparable between the SIDEKICK (DPPC) and manual (POPC) data sets. There were 10 replicates $\times 5 \frac{\mu_S}{replicate} = 50 \,\mu\text{s}$ total for each of the manual FGFR3 conditions. The 98 WT, 96 heterodimer, and 92 mutant FGFR3 0.5 μ s replicates accumulate 49,

48, and 46 μs of total simulation time, respectively. Although each FGFR3 condition can be compared over roughly 50 μs of total simulation time, it is noteworthy that the much larger number of SIDEKICK replicates results in more simulation restarts, and therefore less time spent in the dimer configuration.

The fixed_helix_thermal_merged_SIDEKICK() and thermal_bins_SIDEKICK() functions in the dimer_geometric_tools.py module (page 356) were called in sequence by the head script (analyze_sidekick_FGFR3_dimer_simulations.py) to produce the probability map for the position of helix 2 in the reference frame of rmsd-fixed helix 1. The comparison between FGFR3 dimer interfaces in POPC and DPPC is shown in Figure 5.55 on page 180. Clearly, the primary dimer interface is still located at the 'bottom left,' which is encouraging for validation as a stable interface. However, the secondary dimer interface is located at the 'top right' in DPPC rather than the 'bottom right' observed for POPC. Curiously, the secondary dimer interface in DPPC is more prominent in the WT than the heterodimer, and then reappears in the mutant homodimer.

5.6 FGFR3 Monomer Simulations

I performed a set of FGFR3 monomer simulations in POPC bilayers (see Table 5.2 on page 190) to control for the individual behaviour of the FGFR3 WT and G380R mutant TM peptides used in the dimer simulations. I wrote the preliminary analysis functions for the monomer replicates in the monomer_geometric_tools.py module (page 460), which is controlled by the head script analyze_FGFR3_monomer_simulations.py (page 457).

5.6.1 Helix Tilt Angle

I wrote the helix_tilt_vs_bilayer_normal() function in the monomer_geometric_tools.py module (page 460) to track the tilt of the FGFR3 WT or mutant helices with respect to the bilayer normal in each of the replicate monomer trajectories. The

helical axis was defined as the first eigenvector of the C_{α} backbone and the bilayer normal was defined as the third eigenvector of the POPC phosphate headgroups. Both the WT (*i.e.*, Figure 5.56 on page 181) and mutant (*i.e.*, Figure 5.57 on page 182) monomers exhibited frequent fluctuations in helical tilt angles, mostly between 0° and 30°. This is a wider range of fluctuation than predicted by oriented circular dichroism and neutron diffraction of FGFR3 peptides in POPC bilayers (0° to 20°) (11).

5.6.2 FGFR3 SIDEKICK Monomer Simulations

In addition to the manually executed monomer replicates, the SIDEKICK high-throughput simulation framework (described in section 5.5.5 on page 132) was used to conduct 100 replicate simulations (of 0.1 μ s duration) for each of the WT and G380R FGFR3 TM constructs in POPC bilayers. In contrast to the case for dimer simulations, SIDEKICK allows for the use of POPC and automatically generates a gallery of analysis plots. The peptide bilayer burial depth distributions are plotted for the WT (Figure 5.58 on page 183) and mutant (Figure 5.59 on page 184), and it is clear that the center of the mutant peptide is displaced upward from the center of the bilayer relative to the WT (by at least 1 Å). This is consistent with the introduction of the R residue in the mutant TM segment and the movement of this residue away from the hydrophobic core of the bilayer. Experimental results for FGFR3 peptide constructs in POPC bilayers were consistent with a 5 Å upward (N-terminal) displacement of the R380 residue relative to G380 in the WT (11).

SIDEKICK also automatically produced plots for the FGFR3 WT (Figure 5.60 on page 185) and mutant (Figure 5.61 on page 186) helix tilt angle distributions over all the replicate simulations. Both WT and mutant constructs exhibited similar helix tilt angle distribution modes ~38°. This angle is larger than the upper value of the range predicted by experimental constraints from oriented circular dichroism and neutron diffraction of FGFR3 peptides in POPC bilayers (0° to 20°) (11).

The final analysis completed by SIDEKICK is the distribution of helix rotation

angles (about the helical axis itself). While the WT FGFR3 helix clearly assumes a single favoured rotation angle in the bilayer (Figure 5.62 on page 187), the G380R mutant exhibits a bimodal distribution of rotation angles with a roughly 180° rotation between the preferred configurations (Figure 5.63 on page 188). This added 'flexibility' may contribute to the secondary dimer interface behaviour observed in heterodimer and mutant homodimer (section 5.4.6 on page 118).

5.7 Summary And Conclusions

I started this chapter by describing the medical relevance of the G380R mutation in the TMD of FGFR3—in ~99% of cases it is the underlying cause of achondroplasia (163, 164, 165). CG-MD simulations of the FGFR3 WT homodimer, heterodimer, and mutant homodimer TMDs in lipid bilayers were analyzed in detail (section 5.4 on page 111). I demonstrated that the initial 55 Å separation between helices was sufficient to ensure that there was no bias in the dimer formation process and that the dimers did not dissociate once formed (section 5.4.1 on page 111). A substantial amount of stochastic wandering can occur in the bilayer prior to dimer formation (section 5.4.2 on page 113), and this is also consistent with unbiased dimer formation. FGFR3 dimer constructs all exhibited bimodal helix crossing angles (section 5.4.3 on page 114), but still moved together in the membrane after dimer formation (section 5.4.4 on page 115).

Having confirmed stable and unbiased dimer formation, I parsed the GpA and FGFR3 trajectories for the closest interfacial contacts in the dimers (section 5.4.5 on page 116). I first tested my analytical approach on the GpA constructs and the major contacts parsed from the simulations were consistent with experimental results. This provided confidence for the application of the analysis to FGFR3 and I identified at least three major interfacial residues—G370, A374, and R397. The latter residues were consistent with experimental and medical findings, and are suggested as candi-

date interfacial residues for FGFR3 dimers (for which no high-resolution structures are currently available). The three FGFR3 dimer constructs all have a consistent primary dimer interface, but also a secondary dimer interface that appears progressively in the heterodimer and is most prominent in the mutant homodimer (section 5.4.6 on page 118). I demonstrated that the FGFR3 helical positions are more stable at the primary interface than the secondary interface, and that there is a discrete time spent at each interface rather than a continuous sampling between the two interfaces (section 5.4.7 on page 120). Attempts to manually select representative dimer interface structures based on the polar θ of helix 2 in the rmsd-fixed reference frame of helix 1 were problematic because there is a stochastic component to the manual selection procedure that can select a representative primary interface structure that has either a left- or right-handed helix crossing angle (section 5.4.8 on page 121).

For a rigorous classification of FGFR3 dimer interfaces, I parsed across the frames of all trajectories to define *populations* of simulation frames that fall into the primary, secondary, and 'other' interfaces based on moving average (sliding window) polar θ and a filter for sudden short-lived fluctuations in the data (section 5.4.9 on page 123). The results were consistent with a loss of symmetry at G370 and R397 at the secondary interface compared with the primary interface. These interfacial differences are at important contacts (based on simulation and experiment) and are consistent with rotation of one helix relative to the other—a potential molecular mechanism for pathology. In support of this model, activation of ErbB2 occurs by a 120° rotation of the TMD monomers relative to each other after ligand binding to the RTK (197). In addition, the oncogenic V664E TMD mutation in Neu (rat homologue of ErbB2) prevents conformational switching between the active and inactive states (198). Thus, activating RTK TMD mutations may encourage or restrict the rotation of TMDs depending on the specific structure of the RTK.

In section 5.5 (page 126) I analyzed some properties of the POPC bilayer local

and distal to the FGFR3 TMD peptides. There was peptide-local bilayer thinning for GpA and (to a lesser extent) for FGFR3. Curiously, I found that all three FGFR3 dimer constructs dissociated in DPPC but not in POPC, and that the secondary dimer interface and its trends are different in DPPC (section 5.5.5 on page 132).

FGFR3 monomer simulations in POPC were consistent with increased vertical (N-terminal) displacement of the mutant monomer from the center of the bilayer (relative to FGFR3 WT) (section 5.6.2 on page 135), similar helix tilt angle distributions (relative to the bilayer normal), and the presence of two preferred rotation (about the helical axis) angles for the mutant constructs (and only a single preferred rotation angle for the WT). The latter observation may relate to the observed secondary dimer interface for dimer constructs involving G380R and may in particular explain the ability of this helix to rotate in the membrane between the two interfaces.

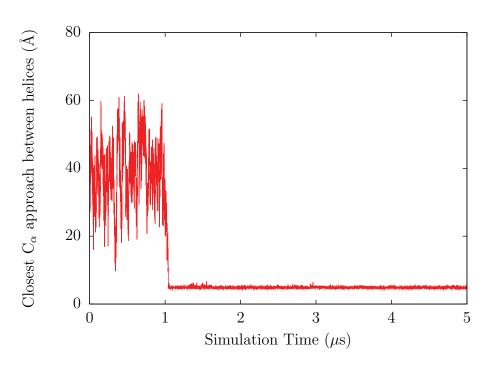

Figure 5.2: Tracking closest C_{α} helix-helix approach for the third WT FGFR3 coarse-grained simulation.

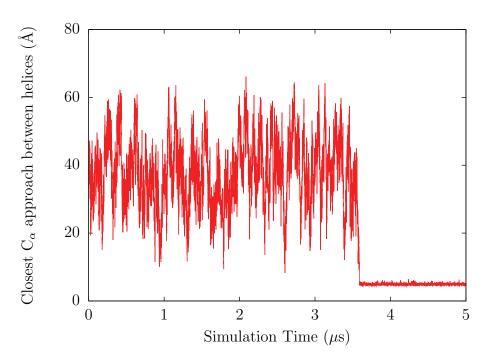

Figure 5.3: Tracking closest C_{α} helix-helix approach for the ninth FGFR3 heterodimer coarse-grained simulation.

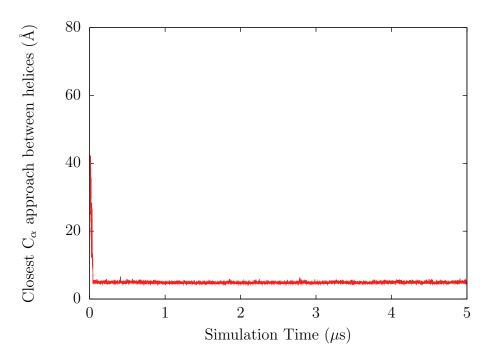

Figure 5.4: Tracking closest C_{α} helix-helix approach for the second FGFR3 mutant homodimer coarse-grained simulation.

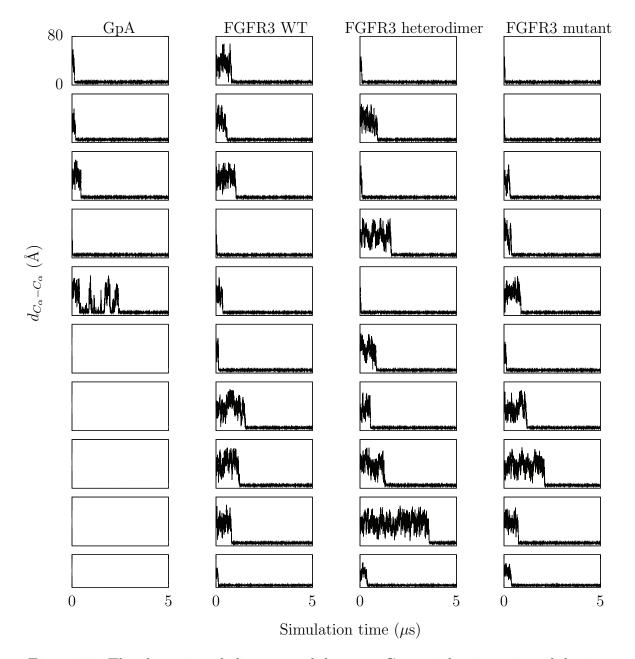

Figure 5.5: The closest interhelix approach between C_{α} particles is monitored during the 5 μs coarse-grained simulations. Five replicates were conducted for GpA, while ten replicates were completed for each of FGFR3 wild-type, G380R heterodimer, and G380R mutant homodimer conditions.

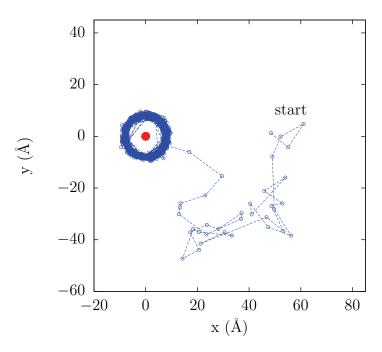

Figure 5.6: Relative motion of the center of geometry of helix 2 (blue) in the reference frame of the center of geometry of helix 1 (red) during the first wild-type homodimer GpA coarse-grained simulation (every 10th frame).

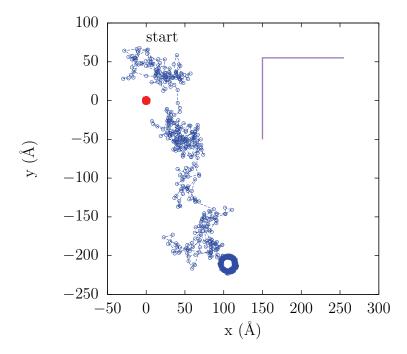

Figure 5.7: Relative motion of the center of geometry of helix 2 (*blue*) in the reference frame of the center of geometry of helix 1 (*red*) during the seventh FGFR3 WT homodimer replicate coarse-grained simulation (every 10th frame). The approximate size of the simulation box in the x-y plane is shown in *purple*.

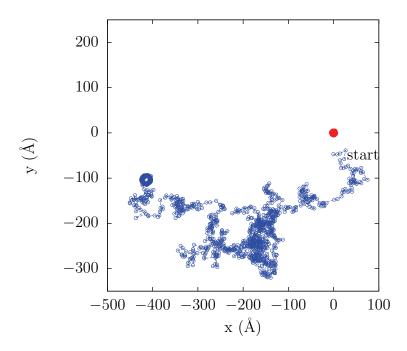

Figure 5.8: Relative motion of the center of geometry of helix 2 (blue) in the reference frame of the center of geometry of helix 1 (red) during the ninth FGFR3 heterodimer replicate coarse-grained simulation (every $10^{\rm th}$ frame).

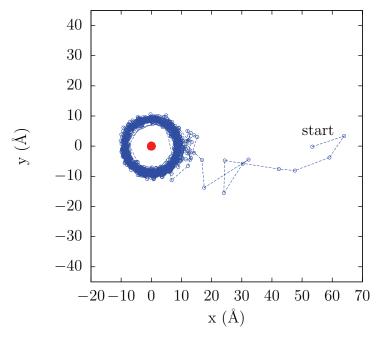

Figure 5.9: Relative motion of the center of geometry of helix 2 (*blue*) in the reference frame of the center of geometry of helix 1 (*red*) during the second FGFR3 mutant homodimer replicate coarse-grained simulation (every 10th frame).

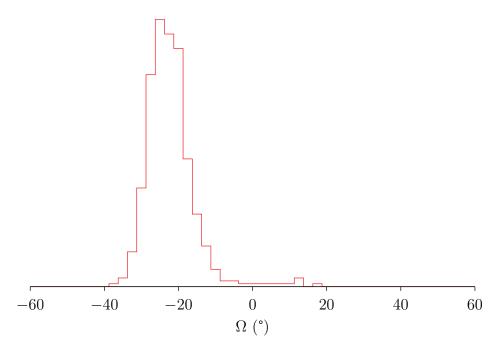

Figure 5.10: Helix crossing angle (Ω) distribution for the first replicate of the GpA WT homodimer construct. Every 25th frame of the trajectory was parsed and included in the histogram only if the helices were dimerized. The area under the curve sums to unity.

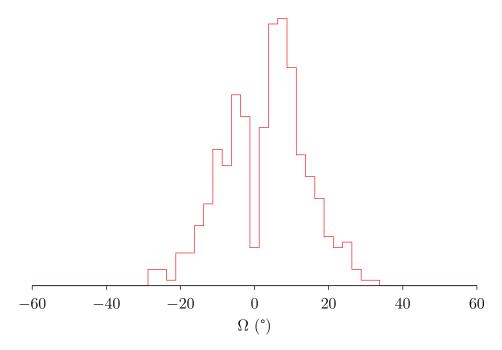

Figure 5.11: Helix crossing angle (Ω) distribution for the first replicate of the FGFR3 WT homodimer construct. Every $25^{\rm th}$ frame of the trajectory was parsed and included in the histogram only if the helices were dimerized. The area under the curve sums to unity.

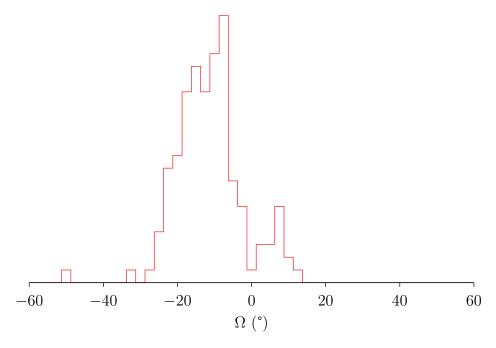

Figure 5.12: Helix crossing angle (Ω) distribution for the ninth replicate of the FGFR3 heterodimer construct. Every $25^{\rm th}$ frame of the trajectory was parsed and included in the histogram only if the helices were dimerized. The area under the curve sums to unity.

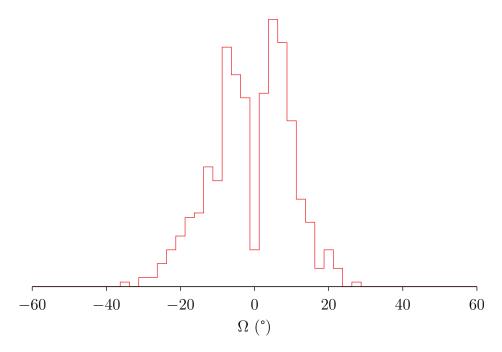

Figure 5.13: Helix crossing angle (Ω) distribution for the first replicate of the FGFR3 mutant homodimer construct. Every 25th frame of the trajectory was parsed and included in the histogram only if the helices were dimerized. The area under the curve sums to unity.

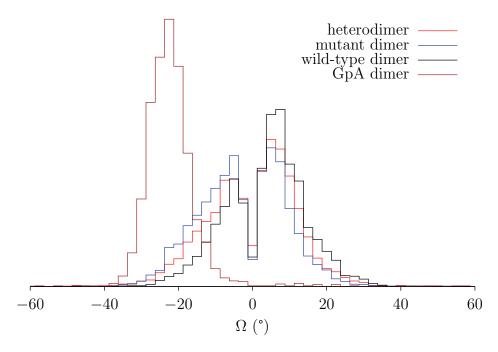

Figure 5.14: Helix crossing angle (Ω) distribution merged over all replicates of GpA and FGFR3 constructs. Every 25th frame of the constituent trajectories was parsed and included in the histograms only if the helices were dimerized. Helix crossing angles are shown for GpA (*brown*), FGFR3 wild-type (*black*), FGFR3 heterodimer (*red*), and FGFR3 mutant homodimer (*blue*). The area under each curve sums to unity.

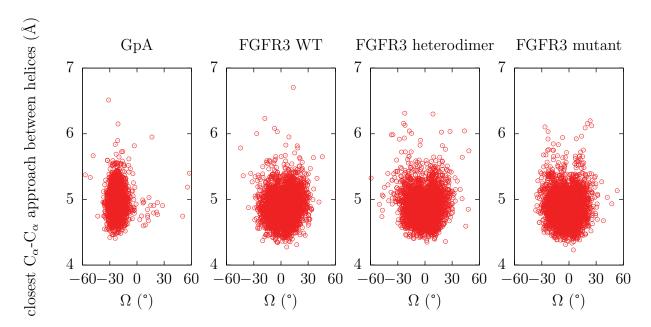

Figure 5.15: Correlating the closest C_{α} interhelical approach with helix crossing angle (Ω) for GpA (5 replicates), FGFR3 WT (10 replicates), FGFR3 heterodimer (10 replicates), and FGFR3 mutant homodimer (10 replicates) constructs. The plotted results are merged across all available replicate simulations as indicated.

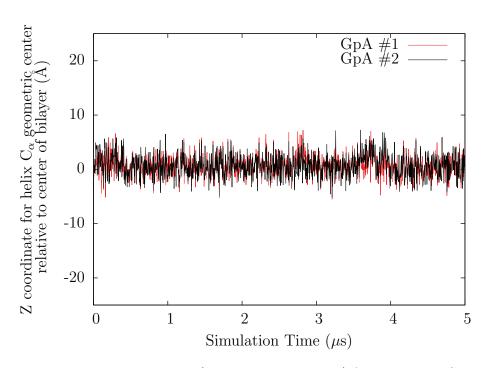

Figure 5.16: Tracking Z coordinate (along bilayer normal) for each helix C_{α} geometric center relative to center of bilayer during the first GpA replicate simulation. Every 10^{th} frame was parsed in a non-centered trajectory.

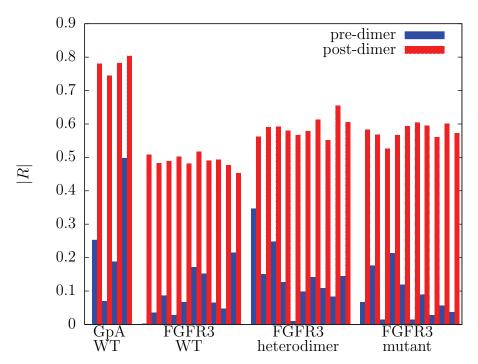

Figure 5.17: The absolute correlation coefficients (|R|) between the Z coordinates of the geometric centers of the GpA or FGFR3 helices in each replicate simulation before and after dimerization. The dimerization distance is defined as a closest interhelical C_{α} approach < 6 Å.

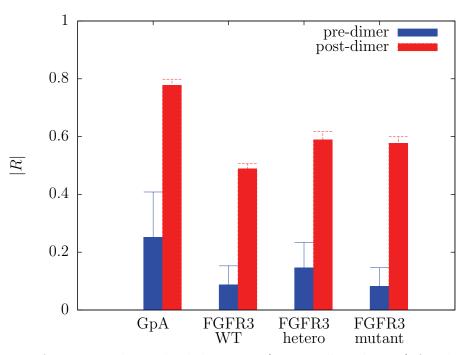

Figure 5.18: Average and standard deviation (across all replicates) for the absolute correlation coefficient (|R|) between helical geometric center Z coordinates for GpA and FGFR3 dimer simulation constructs before and after dimerization. The dimerization distance is defined as a closest interhelical C_{α} approach < 6 Å.

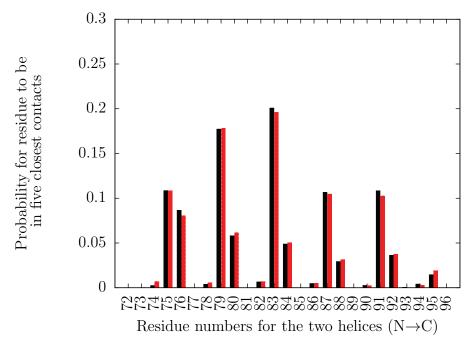

Figure 5.19: The normalized frequency of occurrence for a residue in the five closest contacts between helix 1 (black) and helix 2 (red) when the GpA helix-helix C_{α} separation is within 7 Å in the first replicate coarse-grained simulation.

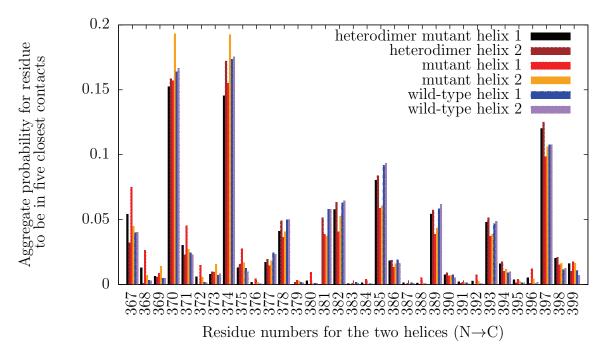

Figure 5.20: Normalized frequency of occurence for a residue in the five closest contacts between helices when interhelix C_{α} separation is within 7 Å over *all* the CG replicate simulations for each of FGFR3 wild-type (helix 1 *blue*, helix 2 *purple*), heterodimer (G380R helix 1 *black*, WT helix 2 *brown*), and mutant homodimer (helix 1 *red*, helix 2 *yellow*) conditions.

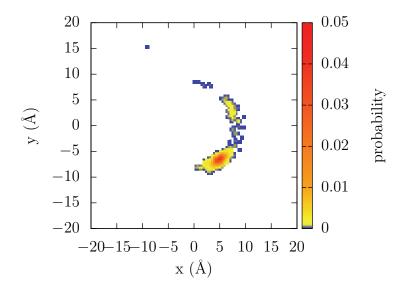

Figure 5.21: A contour plot of the positional probability of GpA helix 2 in the reference frame of rmsd-fixed helix 1 (centered at the origin) in the first GpA replicate simulation. The non-linear probability scale is indexed as $P = 0.0 \ white$, $P = 0.000001 \ blue$, $P = 0.001 \ yellow$, $P = 0.01 \ orange$, $P = 0.05 \ red$.

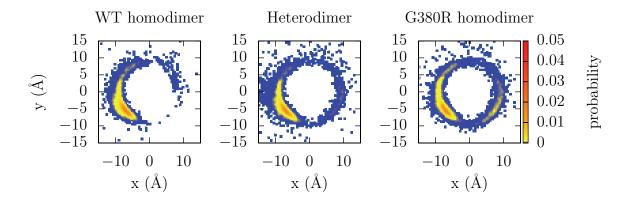

Figure 5.22: A contour plot of the positional probability of helix 2 in the reference frame of rmsd-fixed helix 1 (centered at the origin) calculated over all ten replicate trajectories for each of the FGFR3 dimer conditions. The non-linear probability scale is indexed as P=0.0 white, P=0.000001 blue, P=0.001 yellow, P=0.01 orange, P=0.05 red.

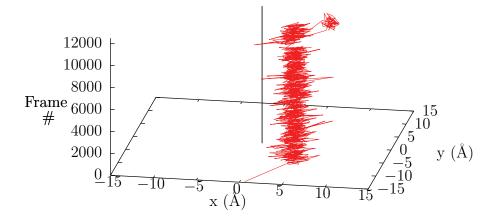

Figure 5.23: The coordinates of the geometric center of helix 2 (*red line*) are tracked in the reference frame of rmsd-fixed helix 1 (central *black line*) as the simulation progresses (with frame number along the Z-axis). This is the fourth replicate GpA CG simulation and is representative of results for other GpA replicates.

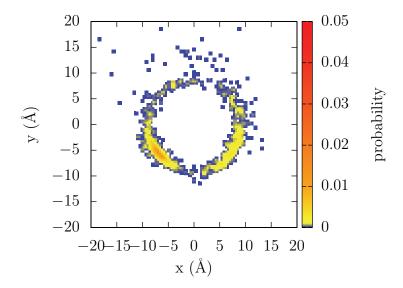

Figure 5.24: A contour plot of the positional probability of helix 2 in the reference frame of rmsd-fixed helix 1 (centered at the origin) in the fourth mutant homodimer FGFR3 simulation. The non-linear probability scale is indexed as P=0.0 white, P=0.000001 blue, P=0.001 yellow, P=0.01 orange, P=0.05 red.

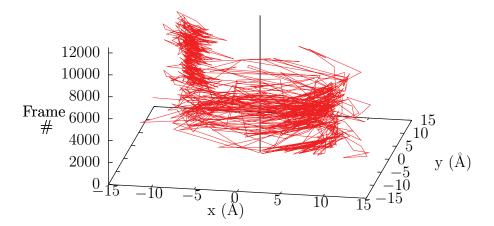

Figure 5.25: The coordinates of the geometric center of helix 2 (*red line*) are tracked in the reference frame of rmsd-fixed helix 1 (central *black line*) as the simulation progresses (with frame number along the Z-axis). This is the fourth replicate FGFR3 mutant homodimer CG simulation and is representative of results for other mutant replicates.

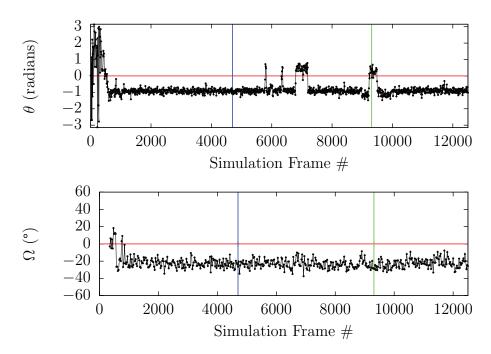

Figure 5.26: Polar angle of helix 2 (θ , top) in the rmsd-fixed frame of helix 1 and helix crossing angle (Ω , bottom) are tracked during the first GpA replicate simulation. Vertical lines are drawn in the respective plots to highlight frames that represent the primary (*blue*, frame 4701) and secondary (*green*, frame 9311) dimer interfaces based on their polar angles. The excursions to the secondary dimer interface are discrete but brief for GpA.

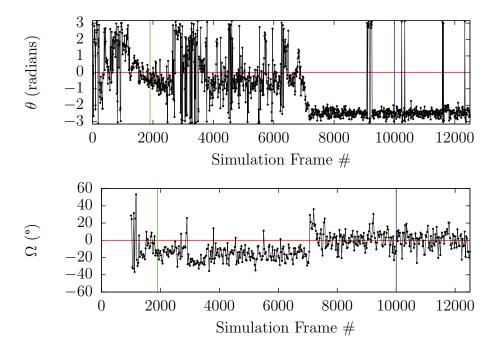

Figure 5.27: Polar angle of helix 2 (θ , top) in the rmsd-fixed frame of helix 1 and helix crossing angle (Ω , bottom) are tracked during the fourth FGFR3 mutant homodimer replicate simulation. Vertical lines are drawn in the respective plots to highlight frames that represent the primary (blue, frame 10001) and secondary (green, frame 1901) dimer interfaces based on their polar angles. There appears to be a transition in Ω that coincides with the dimer interface transition.

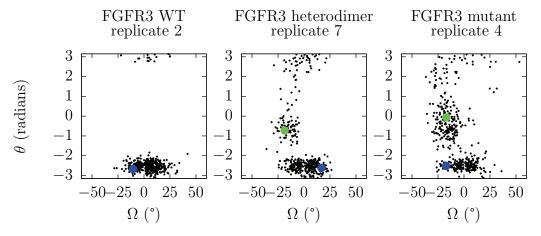

Figure 5.28: Direct correlation of polar angle (θ) and helix crossing angle (Ω) for the frames of representative FGFR3 simulations. The specific primary (blue) and secondary (green) representative dimer interface frames selected by the manual procedure are highlighted as appropriate.

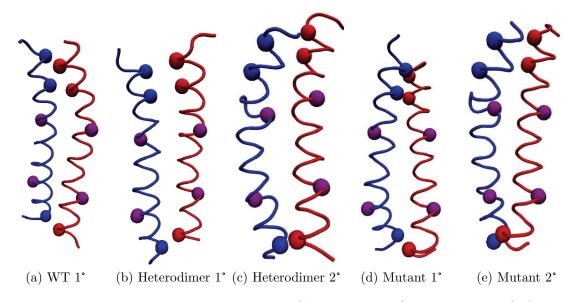

Figure 5.29: Representative coarse-grain C_{α} structures (N-terminus top) for the FGFR3 primary and secondary dimer interfaces. G370, A374, and R397 (which are among the predominant interfacial contacts in Figure 5.20 on page 153) are shown in van der Waals representation, and disease-target residues G/R380 and A391 are in *purple*. Similar secondary interface structures for heterodimer (c) and mutant (e) reflect right-handed crossing angles while differences between primary interface structures reflect (in part) variation in helix crossing angles (which have a bimodal distribution at the FGFR3 primary interface as highlighted in Figure 5.28 on page 160)

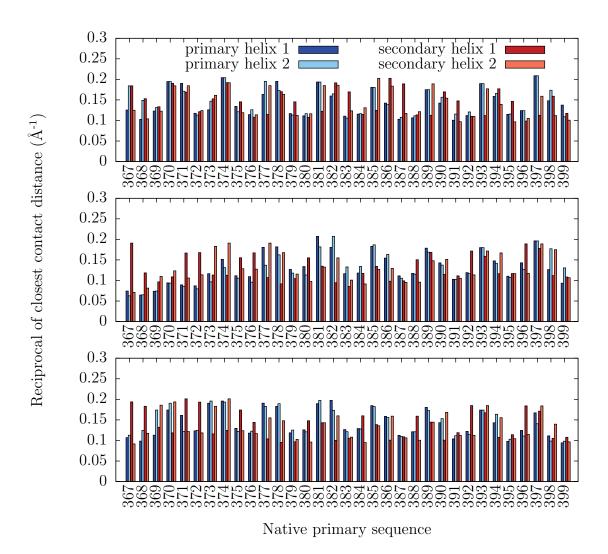

Figure 5.30: FGFR3 WT (top), heterodimer (middle), and mutant homodimer (bottom) reciprocal closest contact distances for each residue in each helix of a representative dimer interface structure.

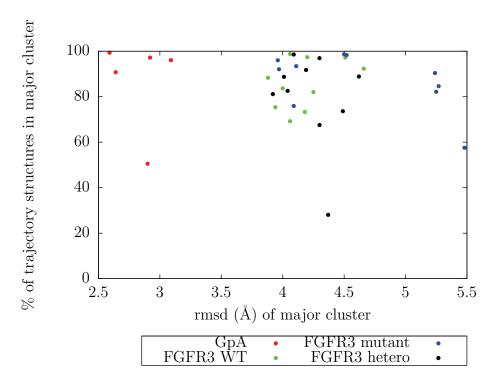

Figure 5.31: Comparing coarse-grained MD simulation trajectory structural clustering by the single linkage method (0.4 nm cutoff; every $10^{\rm th}$ frame parsed). The fifth replicate GpA simulation has a smaller % incorporation to the major cluster because one of the helices assumes an in-plane orientation during part of that simulation. An even smaller % incorporation is observed for the $9^{\rm th}$ replicate FGFR3 heterodimer simulation because of the nearly 4 μ s time required for dimerization.

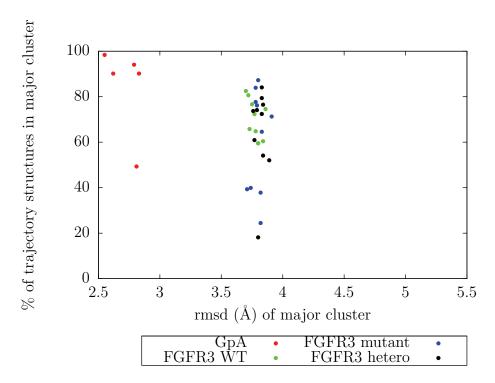

Figure 5.32: Comparing coarse-grained MD simulation trajectory structural clustering by the gromos algorithm (0.4 nm cutoff; every $10^{\rm th}$ frame parsed). The fifth replicate GpA simulation has a smaller % incorporation to the major cluster because one of the helices assumes an in-plane orientation during part of that simulation. An even smaller % incorporation is observed for the $9^{\rm th}$ replicate FGFR3 heterodimer simulation because of the nearly 4 μs time required for dimerization.

Chapter 6

Spitz-Rhomboid Simulation

6.1 Introduction

The spitz-rhomboid system was described in section 4.1 (page 58) as a prelude to describing production and purification of spitz (or homologous) TMD peptide constructs. The latter project resulted in several successfully synthesized peptides that proved extremely difficult to purify. While it was possible to collect NMR spectra for one construct, it was not possible to fully assign resonances and determine the high-resolution structure. In this chapter I use coarse-grained molecular dynamics simulations to study the interaction of E. coli GlpG (ecGlpG) and a spitz construct in a POPE bilayer. POPE has been used because ecGlpG is active when reconstituted in PE lipids but not in PC lipids (199). The simulation setup and analysis is very similar to that described in chapter 5 (page 108) for FGFR3. Because the methodology and source code are detailed in the previous chapter, I will not be as comprehensive in describing similar methods employed in this chapter. A simple objective of these CG-MD spitz-rhomboid studies is to determine if there is a preferential interaction face between enzyme and substrate (i.e., do they preferentially interact near TM5 the putative substrate gate (148)?) Atomistic simulations have been reported for ecGlpG in POPC and POPE bilayers, but the time scales were short and substrate was not included (195). The CG-MD simulations analyzed in this chapter allow for μ s timescales that include both enzyme and substrate in a lipid bilayer. In total, 20 replicates were performed—two sets of $10\times5~\mu$ s replicates with different spitz starting positions relative to ecGlpG to discourage any association bias.

6.2 Tracking Enzyme-Substrate Separation

A CG representation of the 34-residue spitz TMD construct detailed in section 4.3 (page 61) was placed 70 Å from the geometric center of coarse-grained ecGlpG (PDB: 2IC8, (4)) and the closest C_{α} interprotein separation between the two constructs was monitored. While there were replicates where spitz rapidly associated with TM5 (*i.e.*, Figure 6.1 on page 196), this was not normally observed (*i.e.*, Figure 6.2 on page 197). Thus, the spitz TMD construct does not appear to preferentially associate with TM5 despite evidence that TM5 serves as the substrate gate (148).

6.3 Position Of Spitz In Fixed Rhomboid Reference Frame

The previous section (6.2 on page 192) suggests that spitz does not preferentially associate with TM5 when it first encounters rhomboid, but it is cumbersome to assess the preferred position of spitz over all replicate simulations using the described plots. To gauge the position of spitz relative to each ecGlpG TM segment over all replicate simulations, the configuration of ecGlpG was rmsd-fixed to a reference structure and the positional probability of the geometric center of the spitz TMD construct was monitored in this reference frame. To avoid bias, this analysis was performed for ten replicate simulations where spitz was placed nearer to ecGlpG TMs 1 and 3, or in the opposite corner and nearer TM5 but the same distance from the geometric center of ecGlpG (Figure 6.3 on page 198). Although placing spitz nearer TM5 did increase the likelihood of association at that location, the preferred location of interaction was near ecGlpG TM1 for both starting positions. It may be possible that initial interaction (capture) between enzyme and substrate occurs near TM1 even if the actual gate is

on the other side of the enzyme. In addition, both starting configurations clearly allow for interaction of spitz with various rhomboid TM segments, and this sampling is consistent with an unbiased simulation setup.

6.4 Analysis Of The POPE Lipid Bilayer

The previous section (6.3 on page 192) provides evidence for unbiased simulation conditions and a potential enzyme-substrate interaction site at ecGlpG TM1. However, it is not clear how the lipid bilayer is influenced by the presence of the enzyme, the substrate, and their mutual interaction. As described above, ecGlpG activity is sensitive to the lipid headgroup type when reconstituted, and ecGlpG atomistic simulations suggest a ~4 Å thinning of the bilayer in the vicinity of the enzyme (but not the substrate) (195). Before investigating the protein-local and -distal bilayer thickness, I tested for spontaneous phospholipid flip-flop between bilayer leaflets to ensure that I could use the strategy for bilayer thickness analysis detailed in section 5.5 on page 126 for FGFR3. None of the ten tested replicates (spitz starting near ecGlpG TMs 1 and 3) exhibited flip-flop activity (not shown). I also validated that counting lipids in a local shell within 16 Å of the proteins captured a sufficiently large number of phosphates to measure the leaflet interphosphate bilayer thickness proximal to the proteins (not shown). The average protein-local (within 16 Å) and -distal bilayer thickness values are summarized in Figure 6.4 on page 199. The results are reasonably consistent with the ${\sim}4$ Å proximal bilayer thinning reported for ecGlpG in atomistic bilayers (195), while less bilayer thinning is observed near spitz until it associates with rhomboid. The larger standard deviation observed for spitz-proximal bilayer thickness relative to ecGlpG is consistent with a smaller number of captured (local) lipids in the former versus the latter case because of their vast size difference. There is no additional thinning of the bilayer near ecGlpG after association with spitz, despite the suggestion in (195) that this may occur.

6.5 Identification Of Predominant Interprotein Contacts

There is additional confidence in the quality of the CG simulations after confirming that they are unbiased and that the CG lipids reflect the protein-local behaviour observed in an atomistic context. I began a more in-depth analysis of the interaction between the spitz construct and ecGlpG by parsing out the predominant interprotein contacts from a set of replicate simulations as detailed for FGFR3 in section 5.4.5 (page 116). The results are summarized for each of the spitz construct residues from the first ten replicate simulations (spitz starting near ecGlpG TMs 1 and 3) in Figure 6.5 on page 200. The predominant contacts are located at the N- and C-termini and around the putative ASIASGA consensus sequence (200). It should be noted that the substrate consensus sequence for cleavage is now known to be substantially less specific (141).

Having identified spitz construct residues which interact with ecGlpG, the reciprocal question arises—which residues on ecGlpG interact with the substrate? Using the same methodology for the much larger rhomboid construct produces a cumbersome set of contact probability plots for each of the TM segments and loops (not shown). A more natural approach includes a third dimension to indicate the bilayer burial depth of the residue because this information helps gauge the topological (rather than merely sequential) context within ecGlpG. A representative contact plot for the first ecGlpG helix is shown in Figure 6.6 on page 201, and it is a common theme among most ecGlpG TM segments that the N- and C-terminal residues are predominantly involved in close contacts with the substrate. This is not surprising given that the spitz construct mirrors—with N- and C-terminal residues primarily involved. It was also striking that helix 4 (which contains the catalytic Ser) had almost no contacts with the substrate (not shown), and this is consistent with its protected position in the center of the protease. The full set of ecGlpG top contacts (with the spitz TMD

construct) are summarized in the structure in Figure 6.7 (page 202). It is clear that the predominant interfacial contacts are located at the N- and C-terminal ends of TM segments and in loops between TM segments.

6.6 Conclusions

Despite recent evidence that ecGlpG TM5 serves as the substrate gate (148, 149), the CG-MD simulations indicate that a preferential interaction may occur between spitz and ecGlpG TM1. The spitz TMD construct was able to sample several ecGlpG interaction faces—consistent with an unbiased simulation setup regardless of the precise starting configuration. Protein-lipid interactions were investigated because of the sensitivity of the enzyme to headgroup type, and the ~4 Å bilayer thinning we observe near ecGlpG is consistent with reported atomistic simulations (195), providing confidence in the retention of crucial behaviours despite the simplifications introduced by the CG model. The CG approach provides the unique opportunity to probe the interactions between enzyme and substrate, and my analysis suggests that the predominant interfacial contacts are at the N- and C- terminal ends of ecGlpG TM segments and in loops connecting the TM segments. The latter results were consistent with predominant interfacial residues on the substrate located at the N- and C- termini. The initial capture of substrate by ecGlpG may thus depend on interactions in the juxtamembrane region rather than more central TM residues, and this is consistent with substrate cleavage sequence competency defined near the N-terminal juxtamembrane region (of type I TM proteins) (141). Additional analysis will include the contact probability filtered by polar angle (see section 5.4.9 on page 123), adaptive Poisson-Boltzmann Solver (APBS) electrostatic analysis, and assessment of ecGlpG rmsd/rmsf during the CG simulations.

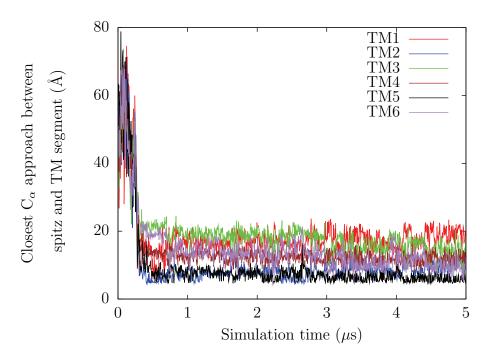

Figure 6.1: The closest interprotein C_{α} separation monitored between spitz and ecGlpG TM segments (as defined in the crystal structure reported in (4)) during the fourth replicate coarse-grained simulation. In this case, spitz associates with TM5 early in the simulation, but this is certainly not observed in most replicates.

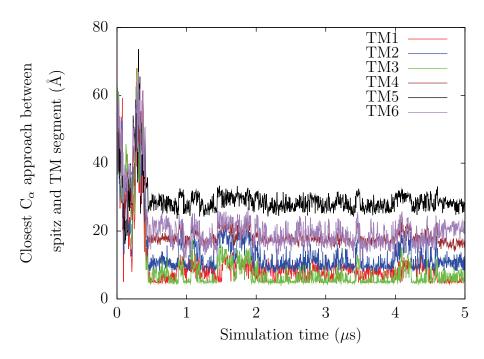

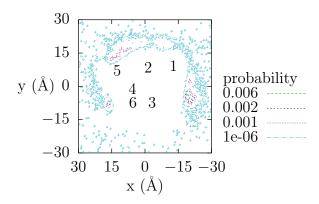

Figure 6.2: The closest interprotein C_{α} separation monitored between spitz and ecGlpG TM segments (as defined in the crystal structure reported in (4)) during the first replicate coarse-grained simulation. In this case, spitz does *not* associate with TM5 early in the simulation, as observed in most replicates.

spitz starting near rhomboid TM 5: $10 \times 5 \mu s$ replicates total

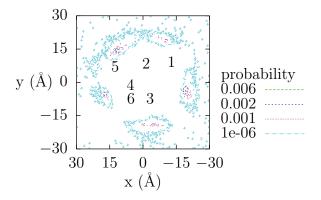

Figure 6.3: The positional probability of the geometric center of the spitz TMD construct is monitored in an rmsd-fixed reference frame (that of rhomboid in the first frame of the first replicate simulation). The ecGlpG TM segment geometric centers are indicated. To avoid any association bias, the starting configuration of spitz was nearer TMs 1 and 3 (top) or TM5 (bottom). Although placing spitz nearer TM5 at the start of the CG simulations appears to increase the likelihood of association at that location, the preferred location of interaction is consistently near TM1. Futhermore, in each case the spitz construct is clearly able to sample multiple interaction faces with rhomboid, and this is consistent with an unbiased interaction between the constructs.

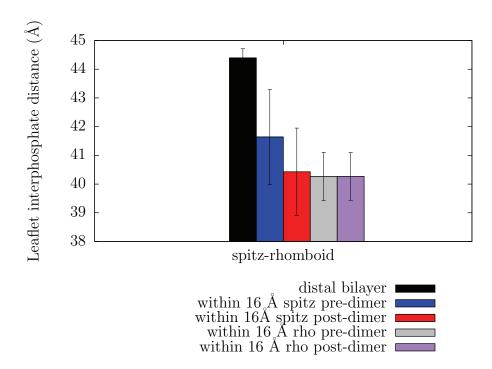

Figure 6.4: Average protein-local and -distal bilayer thickness before and after spitz-rhomboid association (6 Å cutoff) for the ten replicate simulations where spitz starts near ecGlpG TMDs 1 and 3. Error bars display one standard deviation from the mean.

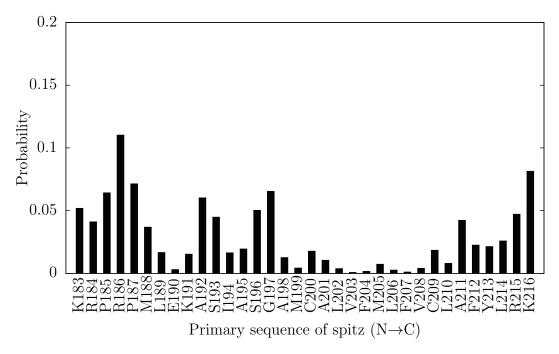

Figure 6.5: The probability for each spitz (TMD construct) residue to reside in the closest contacts with ecGlpG. The exact methodology is described in detail in section 5.4.5 (page 116). The predominant contacts appear to occur at the N- and C-termini, and also around the proposed cleavage consensus sequence (ASIASGA) (200).

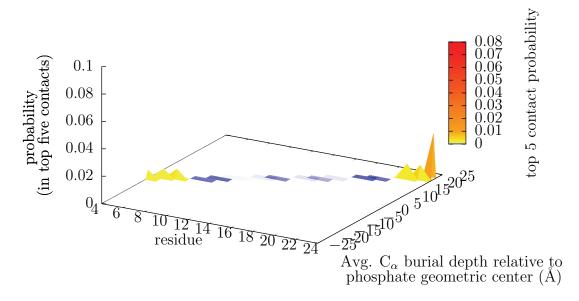

Figure 6.6: The predominant contacts between ecGlpG helix 1 (shown here) and the spitz TMD construct are highlighted and sorted by POPE bilayer burial depth. These results are representative of most ecGlpG helix contact plots, with the N- and C-terminal residues predominantly involved in substrate interaction. The results are aggregated from the first 10 replicate simulations (spitz starting near TMs 1 and 3), and the exact methodology for assessing the predominant contacts is described in detail in section 5.4.5 (page 116)

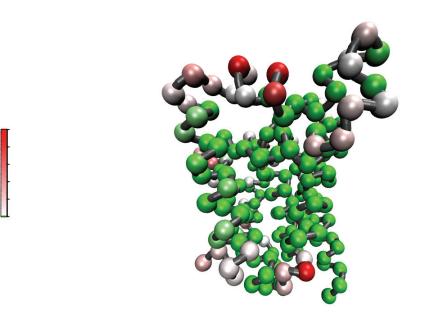

Figure 6.7: The coarse-grained representation of ecGlpG has been simplified to include only C_{α} particles which are coloured based on their close contact probability (see section 5.4.5 on page 116) with the substrate. Water and the lipid bilayer are also excluded for clarity. The probability colour map runs from low (green) \rightarrow medium (white) \rightarrow high (red), with values ranging from 0 \rightarrow 80% (of total close contacts) and is based on the first ten replicate simulations (spitz starting near ecGlpG TM segments 1 and 3). The cytosolic side of ecGlpG is at the bottom and the periplasmic side at the top.

Chapter 7

Conclusions

NMR spectroscopy was used to determine an ensemble of NHE1 TM IX structures in DPC micelles that featured a disruption in helicility near functionally critical residues. A common approach to extend beyond structural information is to probe the flexibility of peptides using NMR spin relaxation experiments. I performed the latter class of experiments for NHE1 TM VII in DPC micelles, and report μ s-ms timescale fluctuations over a critical segment of the peptide. The structural and dynamics results suggest an importance for flexibility in NHE1 TM segments, a theme which has been emphasized in a number of NHE1 TM segment studies (22, 27, 201, 137). It is, however, not yet possible to unambiguously assign the membrane-spanning topology of each NHE1 TM segment to either of the two proposed topologies (13, 14). This will likely require the crystal structure of full-length NHE1.

The poor tractability of spitz or spitz-related rhomboid protease substrate TMD constructs was quite clear. Although many of the constructs were successfully produced by SPPS, purification by HPLC was problematic. When others attempted to produce spitz constructs using expression techniques in *E. coli*, there were also substantial difficulties with yield and purification. In the case of an apparently pure spitz peptide construct, homonuclear NMR spectra were not sufficient to unambiguously assign resonances. Thus, it is worthwhile to include isotope labels in the peptide production process, but there is no clear route to simplified production and purification.

The rhomboid protease system was investigated from another angle using CG-MD simulations, and the initial results suggest that a preferential interaction between enzyme and substrate occurs near TMs 1 and 3 rather than near the proposed substrate gate, TM 5 (148). Furthermore, ecGlpG and the spitz TMD appear to perferentially interact at the terminal ends of helices rather than within the hydrocarbon core of the bilayer.

An extensive analysis of CG-MD simulations of the FGFR3 dimerization process was presented. This includes an integrated discussion of the algorithms used to parse the simulation trajectories, and the appendix includes extensively-documented source code for these analyses. There is no high-resolution structure of FGFR3 available, and these simulation studies provide insight into residues near the dimer interface and the effect of the G380R mutation in the FGFR3 TMD—which causes achondroplasia (202). Strikingly, residue 380 does not feature prominently at the dimer interface, while G370 is one of the closest contacts in the dimers and is mutated to Cys in type 1 thanatophoric dysplasia, a much more severe skeletal phenotype (191). Thus, the phenotypic severity of an FGFR3 mutation may correlate with the proximity of the mutated residue to the dimer interface. I have also described a secondary dimer interface which progressively appears in the heterodimer and mutant homodimer FGFR3 constructs. The rotation of one helix relative to the other may increase signaling activity which causes the phenotype, a conclusion supported by helix-rotation effects reported to affect the activity of receptor tyrosine kinases (197, 198).

Overall, I have employed complementary techniques from structural biology and computational biochemistry to gain insight into biologically relevant membrane proteins.

Appendix A: Source Code For Fractional Isotope Incorporation In Peptide Mass Calculations

A.1 Introduction

rated during solid-phase synthesis. The website employing this code is available at http://129.173.89.133/cgi-bin/isotope -cgi.py. My code has also been incorporated in the back-end of other online mass calculation tools (see http://structbio.bio This appendix contains the Python source code I wrote for peptide mass calculations involving fractional isotope labels incorpochem.dal.ca/jrainey/mspep/).

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    209
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           211
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   215
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            217
                                                      195
                                                                                                                                         ^{197}
                                                                                                                                                                                                                                                                                                                                              203
                                                                                                                                                                                                                                                                                    201

Appendix B: Additional Data From Spitz Peptide/Protein Production And Purification

- **B.1** Mass Spectrometry Results
- B.1.1 TR-09-1 Construct

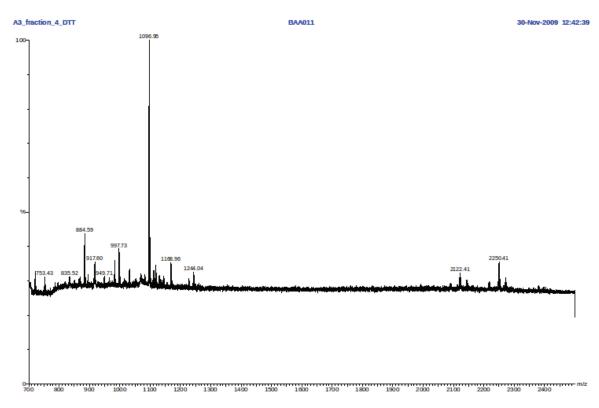

Figure B.1: Fraction 4 from the TR-09-1 crude HPLC run described in Figure 4.12 on page 83 was treated with 200 mM DTT for 1 hour, and then diluted with α -CHC matrix before collecting this reflectron-mode MALDI spectrum. The peak at 2122 m/z is the product missing the N-terminal K while the peak at 2250 m/z corresponds to the desired product. The lower molecular weight compound at 1096 m/z persists in many synthetic spitz fractions.

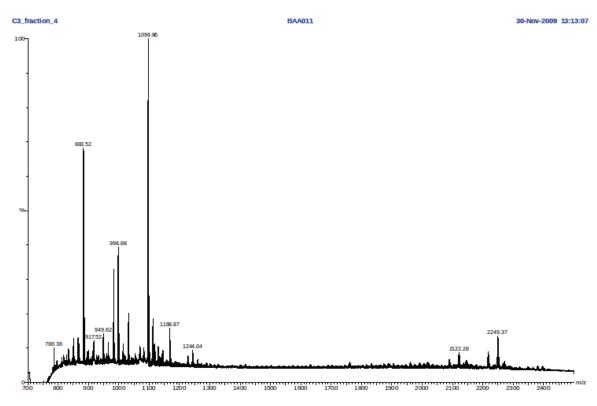

Figure B.2: Similar results are obtained for the TR-09-1 HPLC fraction (#4) used in Figure B.1 (page 217) when there is no DTT pre-treatment.

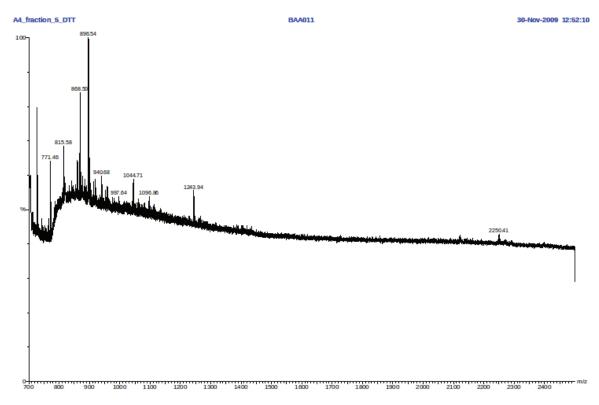

Figure B.3: Fraction 5 from the TR-09-1 crude HPLC run described in Figure 4.12 on page 83 was treated with 200 mM DTT for 1 hour, and then diluted with α -CHC matrix before collecting this reflectron-mode MALDI spectrum. The peak at 2250 m/z corresponds to the desired product, but there are a number of lower molecular weight impurities visible.

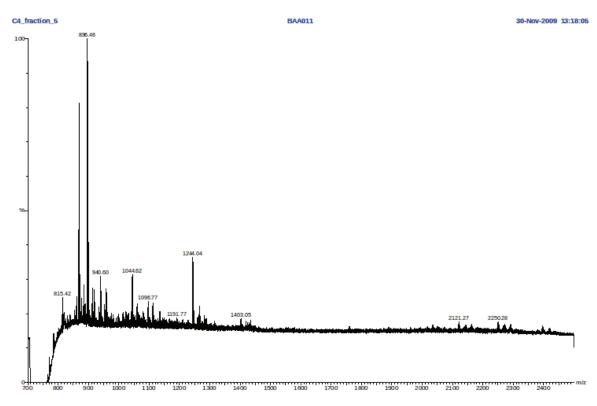

Figure B.4: Similar results are obtained for the TR-09-1 HPLC fraction (#5) used in Figure B.3 (page 219) when there is no DTT pre-treatment.

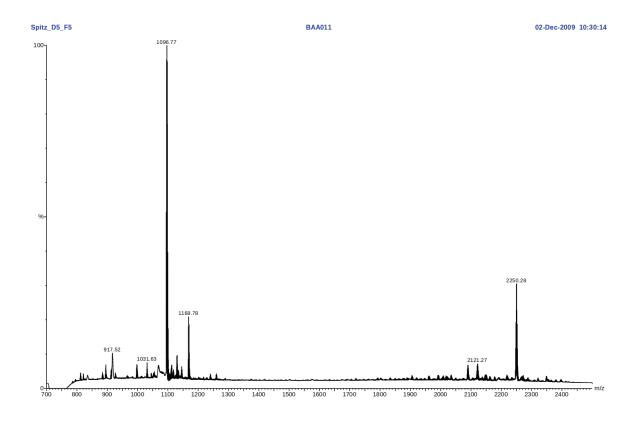

Figure B.5: Reflectron-mode MALDI mass spectrum for fraction 5 (collected between 22-23 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. This is the most promising fraction from the latter HPLC run on the basis of the ratio of the desired product (\sim 2250 m/z) to the product missing the N-terminal K at \sim 2121 m/z (assuming the species have similar ionization potentials).

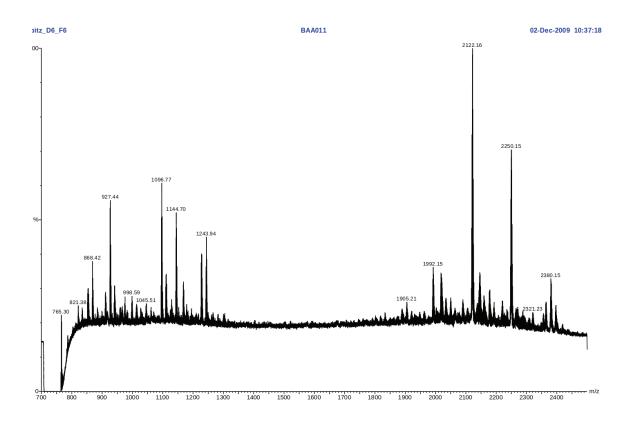

Figure B.6: Reflectron-mode MALDI mass spectrum for fraction 6 (collected between 23-24 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. The desired product is at $\sim\!2250$ m/z while the compound at $\sim\!2122$ m/z is missing the N-terminal K.

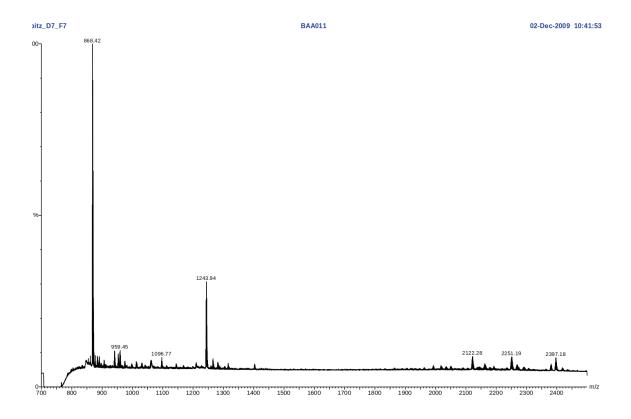

Figure B.7: Reflectron-mode MALDI mass spectrum for fraction 7 (collected between 24-25 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. The desired product is at $\sim\!2250$ m/z while the compound at $\sim\!2122$ m/z is missing the N-terminal K.

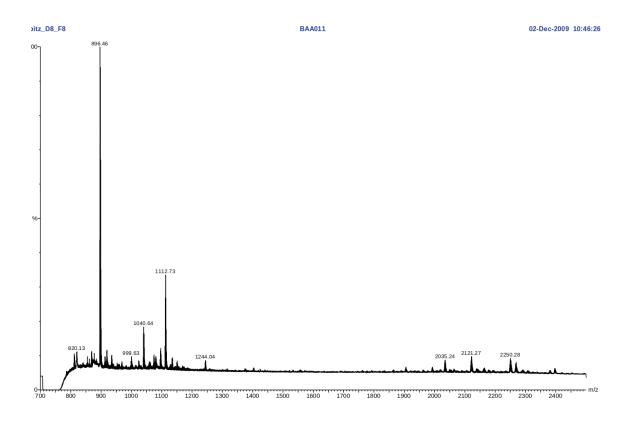

Figure B.8: Reflectron-mode MALDI mass spectrum for fraction 8 (collected between 25-26 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. The desired product is at $\sim\!2250$ m/z while the compound at $\sim\!2122$ m/z is missing the N-terminal K.

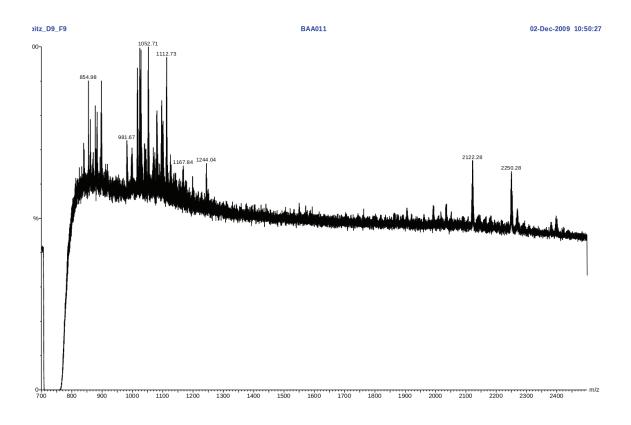

Figure B.9: Reflectron-mode MALDI mass spectrum for fraction 9 (collected between 26-27 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. The desired product is at $\sim\!2250$ m/z while the compound at $\sim\!2122$ m/z is missing the N-terminal K.

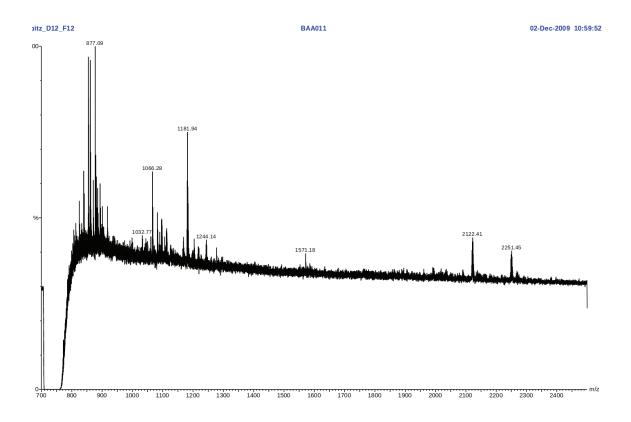

Figure B.10: Reflectron-mode MALDI mass spectrum for fraction 12 (collected between 29-30 minutes) from the crude TR-09-1 HPLC run detailed in Figure 4.13 on page 84. The desired product is at $\sim\!\!2250$ m/z while the compound at $\sim\!\!2122$ m/z is missing the N-terminal K. The product is still eluting 12 minutes after initial detection from the HPLC trace.

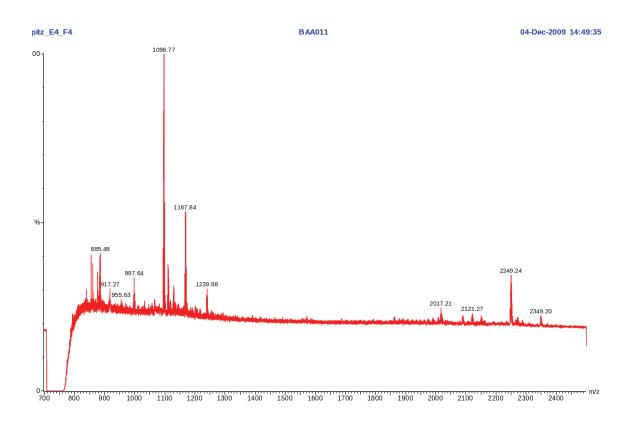

Figure B.11: Fraction #4 (25:01-25:16) from the TR-09-1 C18 HPLC run detailed in Figure 4.15 on page 86 was diluted two-fold with α -CHC matrix and a MALDI spectrum was collected in reflectron mode.

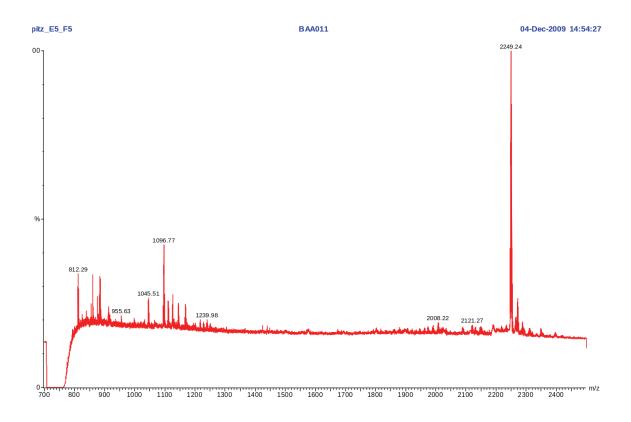

Figure B.12: Fraction #5 (25:16-25:31) from the TR-09-1 C18 HPLC run detailed in Figure 4.15 on page 86 was diluted two-fold with α -CHC matrix and a MALDI spectrum was collected in reflectron mode. This is the highest purity TR-09-1 sample obtained to date, with the product peak at \sim 2249 dwarfing most impurities.

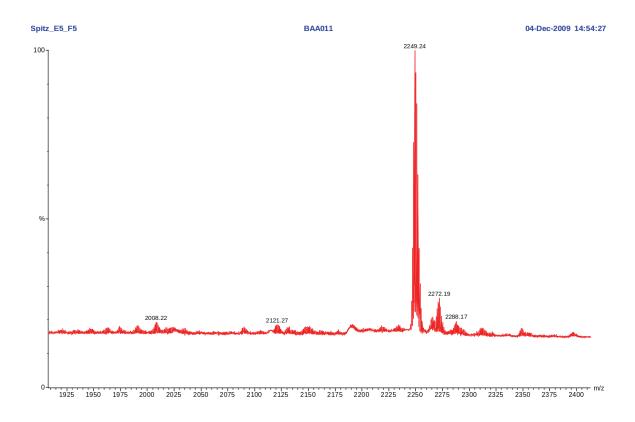

Figure B.13: A zoom-in view of the MALDI spectrum of fraction #5 from Figure B.12 on page 228. The Na $^+$ and K $^+$ adducts of the TR-09-1 product are visible at 2272 m/z and 2288 m/z respectively.

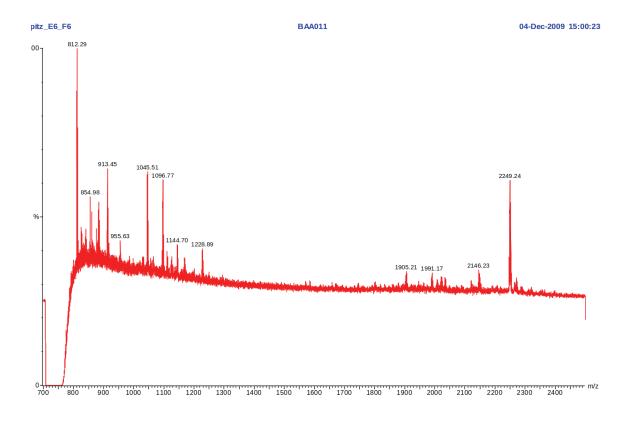

Figure B.14: Fraction #6 (25:31-25:46) from the TR-09-1 C18 HPLC run detailed in Figure 4.15 on page 86 was diluted two-fold with α -CHC matrix and a MALDI spectrum was collected in reflectron mode.

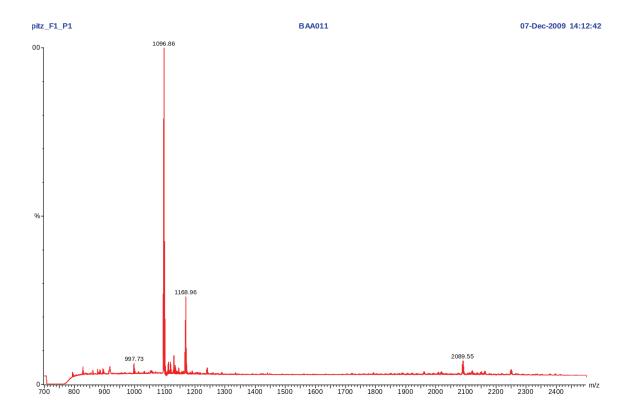

Figure B.15: Fraction #1 from the TR-09-1 C18 semi-preparative HPLC run detailed in Figure 4.17 (page 88) was diluted two-fold with α -CHC matrix and the MALDI spectrum was collected in reflectron mode. The target peak ~2250 m/z is dwarfed by a low molecular weight impurity ~1096 m/z.

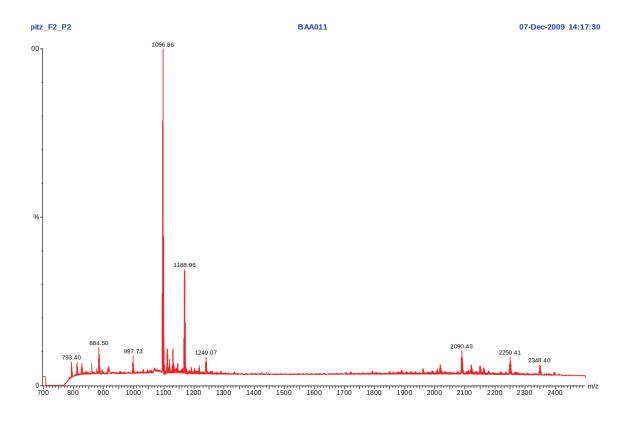

Figure B.16: Fraction #2 from the TR-09-1 C18 semi-preparative HPLC run detailed in Figure 4.17 (page 88) was diluted two-fold with α -CHC matrix and the MALDI spectrum was collected in reflectron mode. The target peak ~2250 m/z is dwarfed by a low molecular weight impurity ~1096 m/z.

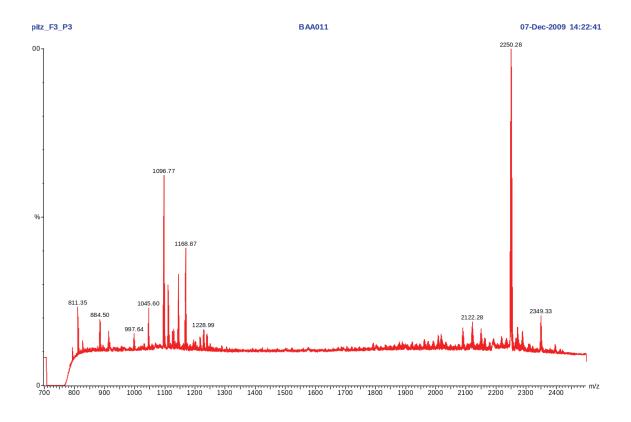

Figure B.17: Fraction #3 from the TR-09-1 C18 semi-preparative HPLC run detailed in Figure 4.17 (page 88) was diluted two-fold with α -CHC matrix and the MALDI spectrum was collected in reflectron mode. The target peak ~2250 m/z is the major peak in the spectrum.

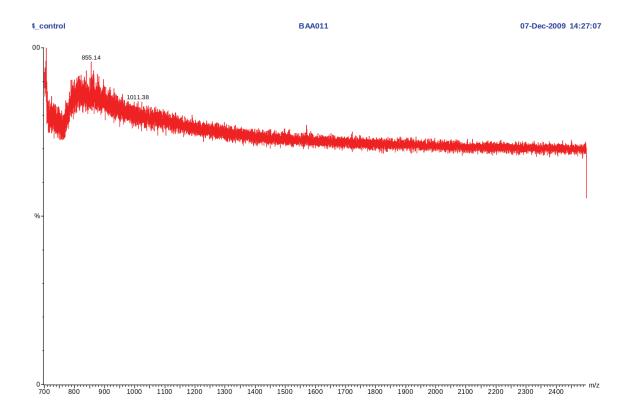

Figure B.18: A blank solution composed of 50% $\rm H_2O/ACN~(0.1\%~TFA)$ was combined with α -CHC matrix to test for low molecular weight impurities which may reside in either the solvents or the matrix. For consistency with test results, the MALDI spectra were collected over the same m/z range in reflectron mode.

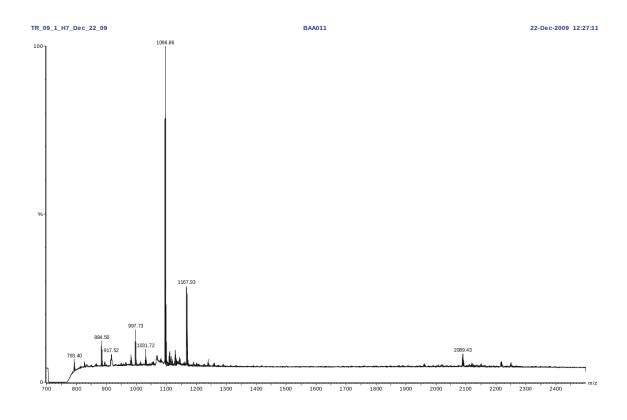

Figure B.19: This is the reflectron-mode MALDI spectrum of a representative fraction (26:40-26:55) from the first crude TR-09-1 bulk purification HPLC run detailed in Figure 4.21 on page 92. The fraction was diluted two-fold with α -CHC matrix prior to collection of the spectrum. The ubiquitous impurity at ~1096 m/z dwarfs the target product at ~2250 m/z.

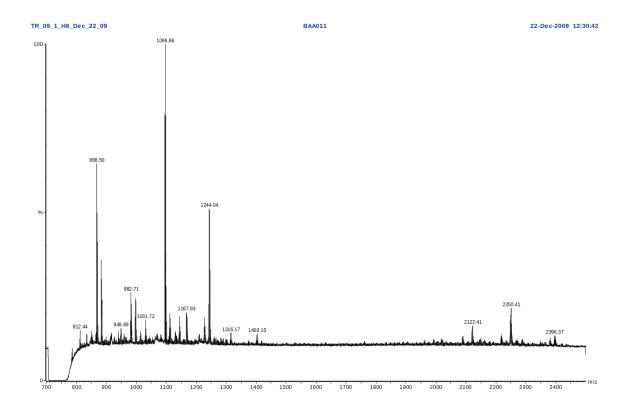

Figure B.20: The most promising MALDI-MS result (shown here) for the first TR-09-1 bulk purification run detailed in Figure 4.21 on page 92 actually correponds to the recovery solution of eluent that flanks the collected fractions between 22-30 minutes. Given the apparent viscosity of the crude TR-09-1 preparation and the trace amount of target product in the collected fractions (see summary Table 4.5 on page 104 and a representative result in Figure B.19 on page 235) it appeares likely that I need to collect fractions later in the HPLC run.

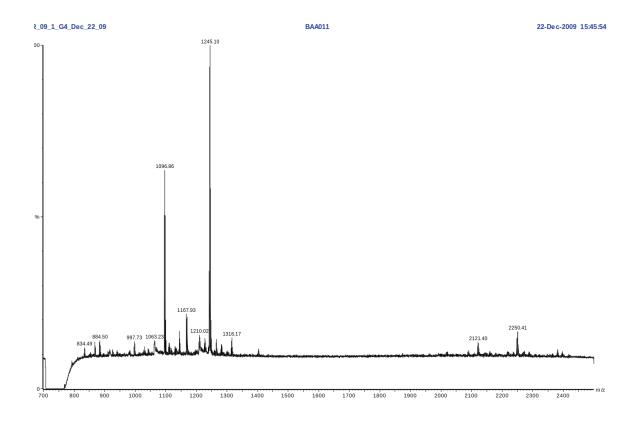

Figure B.21: MALDI reflectron-mode spectrum for the first fraction collected (26:55-27:25) from the second TR-09-1 bulk purification run detailed in Figure 4.21 on page 92. The target product ~2250 m/z appears to be present in greater abundance than the truncated product at ~2121 m/z, but both are dwarfed by lower molecular weight impurities.

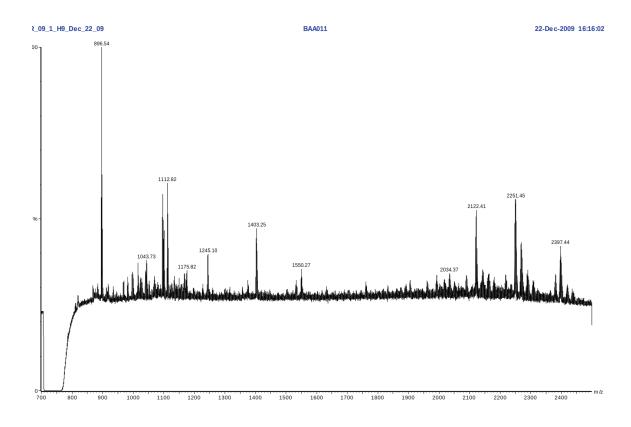

Figure B.22: MALDI reflectron-mode spectrum for the tenth fraction collected (31:25-31:55) from the second TR-09-1 bulk purification run detailed in Figure 4.21 on page 92. This is one of the better results (as summarized in Table 4.6 on page 105) with a fairly prominent ~2250 m/z species. Still, low molecular weight impurities and the truncated product (~2122 m/z) persist.

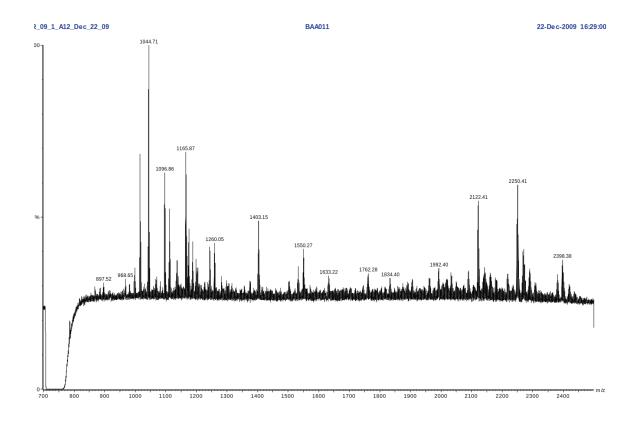

Figure B.23: MALDI reflectron-mode spectrum for the final fraction collected (33:25-33:55) from the second TR-09-1 bulk purification run detailed in Figure 4.21 on page 92. Accounting for the results from the first replicate run (Table 4.5 on page 104), the presence of the target product ~ 2250 m/z here confirms that TR-09-1 elutes from the C18 semi-preparative column over an ~ 8 minute window. This is outrageously poor separation.

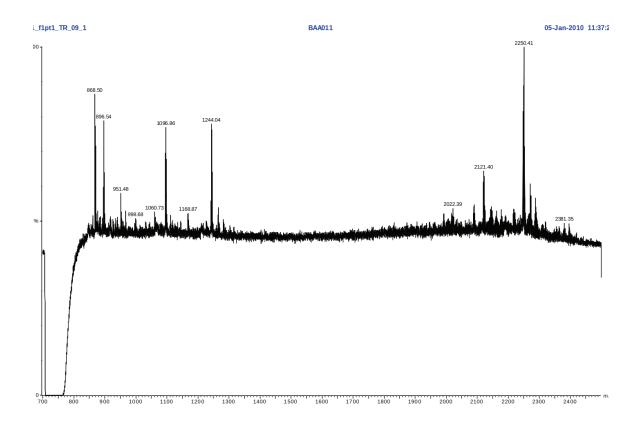

Figure B.24: MALDI reflectron-mode spectrum for the first fraction collected (16-18 minutes) from the TR-09-1 HPLC run detailed in Figure 4.22 on page 93. The target peak $\sim\!\!2250$ m/z is larger than the truncated product at $\sim\!\!2121$ m/z, but (ubiquitous) low molecular weight compounds at $\sim\!\!1096$ m/z and $\sim\!\!1244$ m/z are also co-eluting.

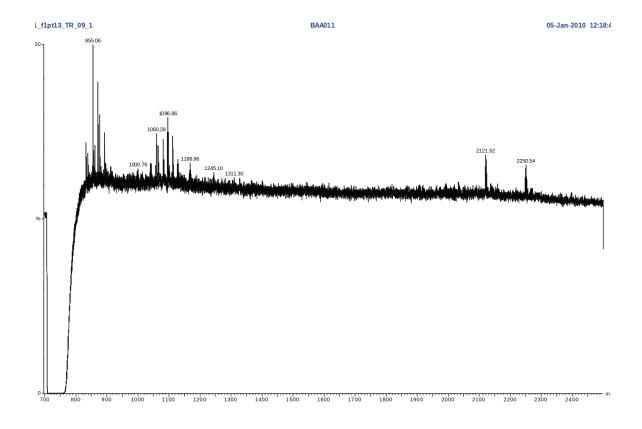

Figure B.25: MALDI reflectron-mode spectrum for the last fraction collected (40-42 minutes) from the TR-09-1 HPLC run detailed in Figure 4.22 on page 93. Despite the fact that this fraction elutes 26 minutes later than the fraction depicted in Figure B.24 (page 240), the product peak at \sim 2250 m/z, the truncated product at \sim 2121 m/z, and low molecular weight impurities at \sim 1096 m/z and \sim 1244 m/z, all persist in the sample.

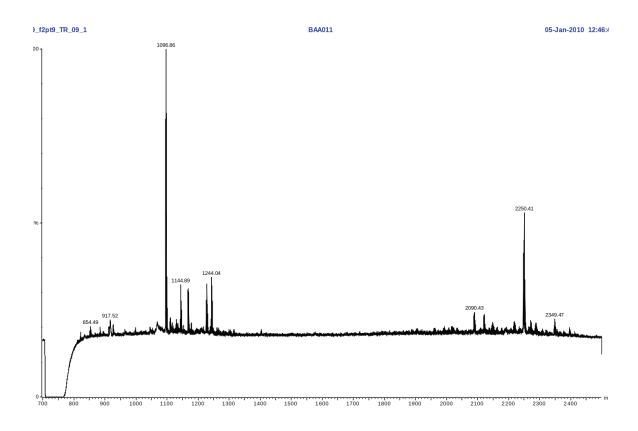

Figure B.26: MALDI reflectron-mode spectrum for the ninth fraction collected (22-24 minutes) from the TR-09-1 HPLC run detailed in Figure 4.23 on page 94. The product peak $\sim\!\!2250$ m/z is prominent, but the ubiquitous low molecular weight compounds at $\sim\!\!1096$ m/z and $\sim\!\!1244$ m/z have clearly co-eluted.

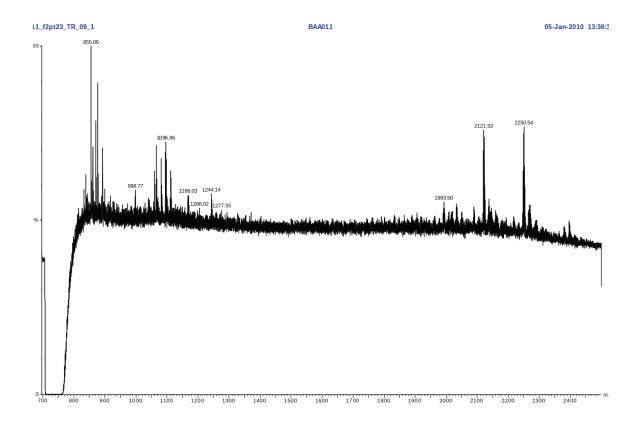

Figure B.27: MALDI reflectron-mode spectrum for the last fraction collected (50-52 minutes) from the TR-09-1 HPLC run detailed in Figure 4.23 on page 94. The product, truncated product, and low molecular weight impurities all continue to elute a full 42 minutes after the inital elution of product (see Table 4.8 on page 106).

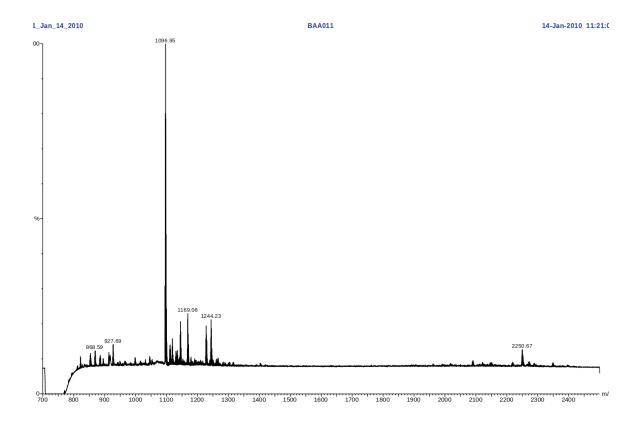

Figure B.28: TR-09-1 fractions collected in the target 22-24 minute window in replicate runs (matching the reference conditions detailed for HPLC purification in Figure 4.23 on page 94) were pooled, lyophilized, and reconstituted in a mixture of deionized water and α -CHC matrix. This reflectron-mode MALDI spectrum is for the first (5.4 mg) of two pooled yields which correctly employed a 2 mL sample loop to match the reference HPLC run. Low molecular weight impurities (most notably the ubiquitous ~1096 m/z species) are present alongside the target product ~2250 m/z.

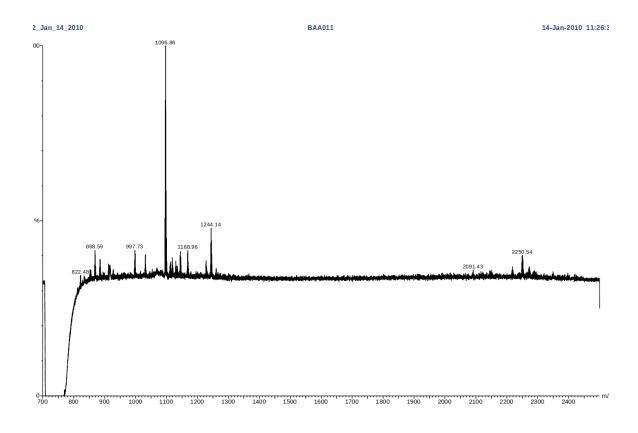

Figure B.29: This is a reflectron-mode MALDI spectrum for pooled TR-09-1 fractions (7.5 mg yield) similar to those described in Figure B.28 (page 244), but collected improperly using a 1 mL sample loop while the reference run employed a 2 mL sample loop. The resulting mass spectrum is effectively the same despite the error, and this is not surprising given the broad elution profile exhibited by TR-09-1.

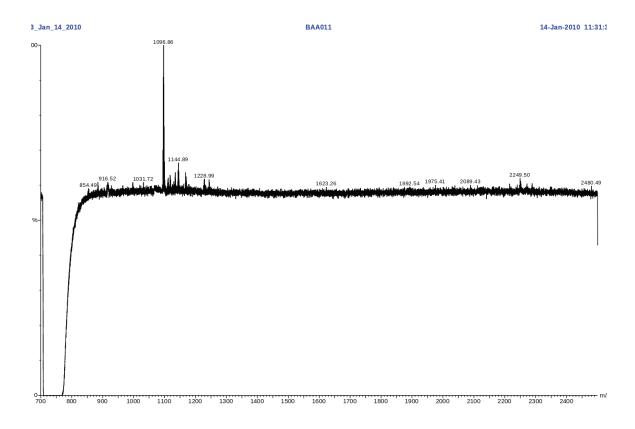

Figure B.30: This reflectron-mode MALDI spectrum was collected for the second pool (11.2 mg yield) of purified TR-09-1 fractions matching the description in Figure B.28 on page 244. Curiously, however, this matching pool of fractions exhibits less target product $\sim\!2250$ m/z relative to the impurity $\sim\!1096$ m/z.

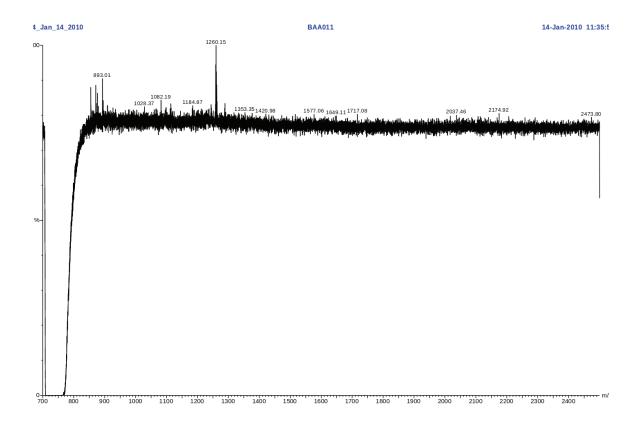

Figure B.31: A 50% DI- $\rm H_2O/\alpha$ -CHC matrix mixture was used as a blank solution for testing the three pooled (partially purified) TR-09-1 fractions above. This MALDI spectrum does not show any substantial indication of the common low molecular weight impurities that permeate the majority of TR-09-1 HPLC fractions.

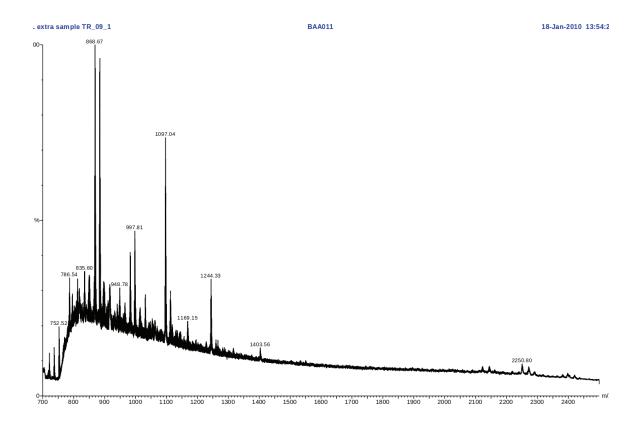

Figure B.32: Eluent collected between 24-52 minutes in TR-09-1 bulk purification runs (which match the reference run detailed in Figure 4.23 on page 94) was lyophilized and reconstituted with deionized water and α -CHC matrix. This reflectron-mode MALDI spectrum demonstrates that the target product ~2250 m/z is still present in the recovered fractions along with the ubiquitous impurities ~1096 m/z and ~1244 m/z.

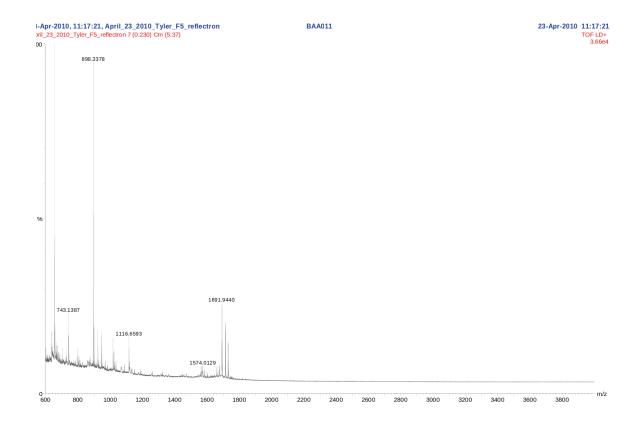

Figure B.33: Fraction 5 (30-36 minutes) from the TR-10-2 HPLC run detailed in Figure 4.27 (page 98) was diluted two-fold with α -CHC matrix and this reflectron-mode MALDI spectrum was collected. The target product is clearly visible ~1691 m/z, and its Na⁺ and K⁺ adducts are also present. However, there is also a low molecular weight impurity ~898 m/z.

B.1.2 TR-10-2 Construct

B.1.3 TR-08-2 Construct

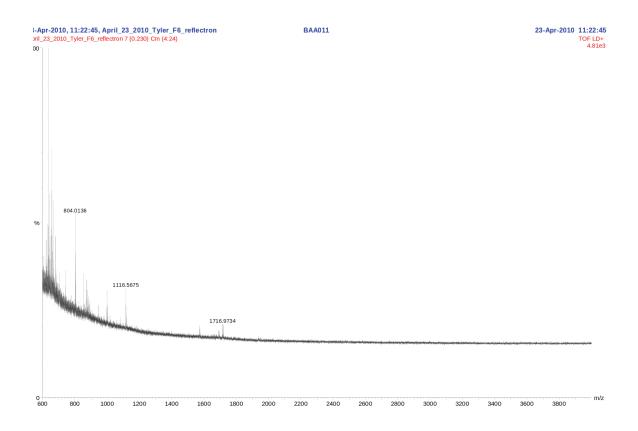

Figure B.34: Fraction 6 (36-42 minutes) from the TR-10-2 HPLC run detailed in Figure 4.27 (page 98) was diluted two-fold with α -CHC matrix and this reflectron-mode MALDI spectrum was collected. The peak \sim 1716 m/z most likely corresponds to the Na⁺ adduct of the target product (\sim 1691 m/z).

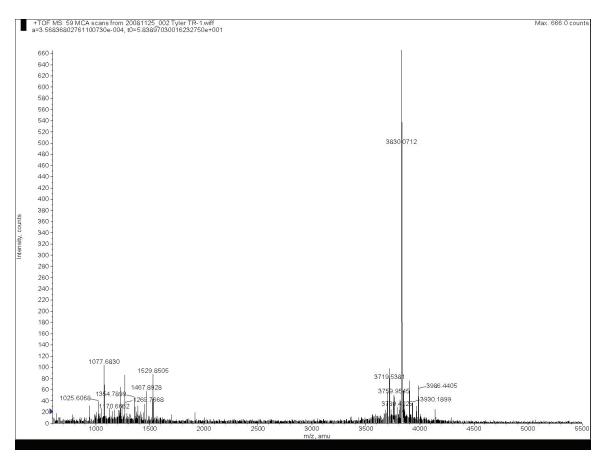

Figure B.35: MALDI spectrum for TR-08-2 fraction #1 from the HPLC run detailed in Figure 4.5 on page 77 demonstrating a relatively pure sample with major peak near the target mass ~ 3830 g/mol.

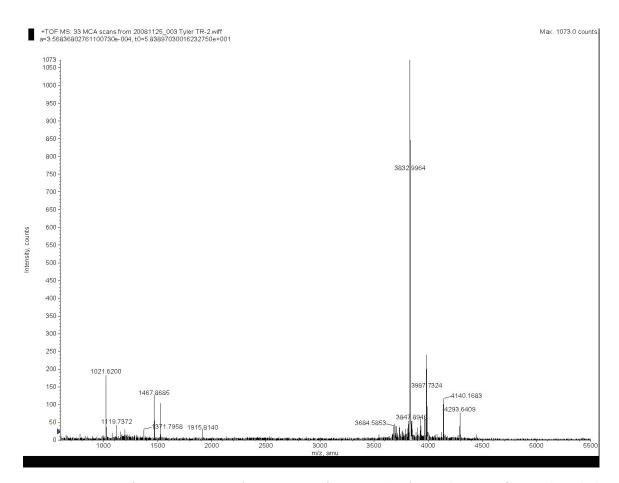

Figure B.36: MALDI spectrum for TR-08-2 fraction #2 from the HPLC run detailed in Figure 4.5 on page 77 demonstrating a relatively pure sample with major peak near the target mass ~ 3830 g/mol. Curiously, a fraction collected earlier in the same HPLC run produced a nearly matching MALDI profile (Figure B.35 on page 251).

Predicts NMR Spin Relaxation Parameter Trends Appendix C: Source Code For Website Which With Magnetic Field Strength

C.1 Introduction

The source code for the online relaxation-plotting program (http://structbio.biochem.dal.ca/jrainey/Tyler_relaxation/) not included all of the front-end html and css code for the website, but the source for the mathematical back-end and some of is written in the Python programming language and uses the cgi module to interact with the web interface user input. I have the user forms are detailed over the following pages.

C.2 Source Code Proper

Appendix D: Source Code For FGFR3 MD Simulation Analysis

D.1 Introduction

This appendix contains the Python (MDAnalysis-based) source code used for parsing the production-length GROMACS trajectories for the FGFR3 CG-MD replicate simulations.

D.2 Python Source Code For Trajectory Parsing With MDAnalysis

Listing D.15: This module (analyze-FGFR3-dimer-simulations.py) recursively moves

```
directory with symlinks to the original production-length
